WATER-RESOURCES APPRAISAL OF THE
SOUTH-ARKANSAS LIGNITE AREA

By J. E. Terry, C. T. Bryant, A. H. Ludwig, and J. E. Reed

ABSTRACT

The feasibility of developing lignite resources in south-central Arkansas is an important question at the present time (1978). Part of the concern is related to the possible impacts that mining and processing of lignite will have on water resources. Not only will the disturbance caused by excavating affect the quantity and quality of surface and ground water but, the mining, processing, and conversion processes will require the use and consumption of significant quantities of water.

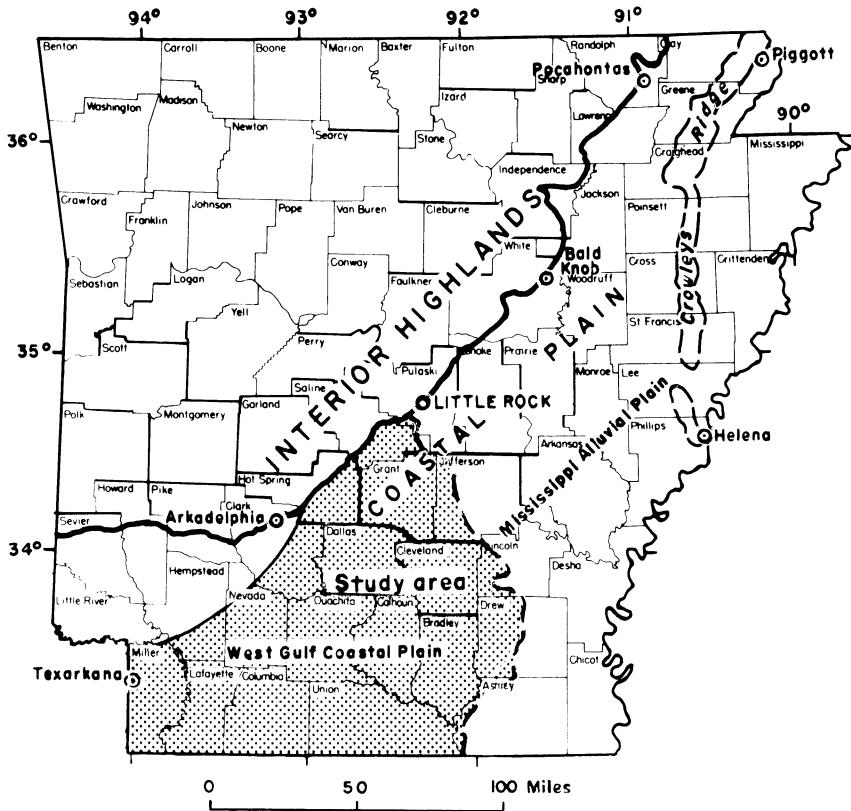

In order to assess the magnitude of the effects of strip mining upon both surface and ground water, baseline conditions (hydrologic conditions in the area prior to mining) must be well defined. A thorough data file and literature search was made so that baseline conditions in the area could be defined. In addition, data-collection networks have been established for the collection of quantitative and qualitative information on streamflow and water levels in the aquifers. Data collected to date at these sites are included in the report. Collection of data at these sites will continue through at least September 1979.

Information presented in this report can be used to estimate the quantities of water available for use and the possible effects of mining and associated dewatering on water resources.

INTRODUCTION

Lignite in Arkansas

Lignite occurs in Arkansas principally in the deposits of Eocene age. These deposits are at the surface and in the subsurface southeast of a line approximately from Texarkana, northeastward through Arkadelphia, Little Rock, Bald Knob, and Pocahontas, to the Missouri State boundary. This line coincides roughly with the western boundary of the Coastal Plain in Arkansas (fig. 1). The area southeast of this line, which is almost one-half of the State, can be divided into three subareas with differing characteristics. The first subarea is a linear upland area called Crowley's Ridge which extends from the Missouri State boundary, north of Piggot, south to Helena. Deposits of Eocene age occur along this ridge. In many places, these deposits of Eocene age are covered by a substantial thickness of younger loess, silt, sand, or gravel. The second subarea is a part of the Mississippi Alluvial Plain, an area of flat terrain suited to agriculture. This area is of interest to lignite producers. However, in the Mississippi Alluvial Plain, the deposits of Eocene age are covered by 100 to 200 ft of alluvial deposits, which underlie the flood plains and terraces of the Arkansas, White, St. Francis, Mississippi, and other rivers. The sand and gravel in the lower part of the alluvial deposits constitute a productive aquifer that furnishes water to thousands of irrigation wells. Removing 100 ft or more of overburden, and pumping large quantities of water from strip mines, will increase the cost of producing lignite in the Mississippi Alluvial Plain. The third subarea includes all or parts of 20 counties in south-central Arkansas that contain outcrops of the deposits of Eocene age. Much exploration by several energy companies has taken place in this area, which contains several prospective lignite mining localities. These 20 counties constitute the most prospective area for development of the lignite resource at the present time.

EXPLANATION

— Boundary of physiographic region - - - - - Boundary of physiographic section

Figure 1.—Location of the project area.

Lignite found in Arkansas has a heating value of approximately 10,000 Btu/lb in dry form or 6,000 Btu/lb as mined. Lignite has a high moisture and volatile content. The high volatile content makes it readily convertible into gas or liquid form; however, the high moisture content and susceptibility to spontaneous combustion present problems in transportation and storage. Arkansas lignite is also low in sulfur content, ranging from 0.3 to 0.8 percent, making it desirable fuel for steam-electric generating plants.

Because it is not economically feasible to transport Arkansas lignite long distances, it will probably be utilized in near mine-mouth operations. Possible uses would include steam-electric generation, gasification, distillation of liquid hydrocarbons, and extraction of waxes.

Location of Project Area

The project area is all or parts of the above-mentioned 20 counties in south-central Arkansas. This area lies within and shares a common eastern boundary with the West Gulf Coastal Plain (fig. 1). East of this boundary, thick, highly saturated Quaternary deposits overlie the Eocene formations. To the northwest, the project boundary is the base of rocks of Eocene age (contact between Midway and Wilcox Groups on the geologic map of Arkansas). The southern and western boundaries are the State boundaries between Arkansas, Louisiana, and Texas.

Purpose and Scope of Investigation

The primary purpose of this investigation is to establish a data base defining hydrologic conditions in the project area prior to lignite mining.

Such an assessment is vital if the possible impacts of strip mining and lignite utilization upon water resources are to be evaluated.

Inevitably, environmental questions will be raised about the mining and utilization of lignite. Along with the more obvious effects on quality and quantity of surface water, strip mining of lignite could have an impact on ground water, both in the vicinity of the mine and at updip and downdip locations. Industries which use the lignite, either as a fuel or as a source for other products, will use and consume certain quantities of water. It is vital to have hydrologic information that can be used to answer both water use and environmental questions and to develop countermeasures to problems that may arise. Establishment of a data base defining predevelopment conditions in the project area is an important goal.

The information that must be contained in such a data base includes the following:

1. The availability and quality of ground and surface water.
2. The location and areal extent of the significant aquifers and their outcrops.
3. Water-level altitudes in the Tertiary aquifers.
4. Thickness of the Tertiary aquifers.
5. The areal extent and thickness of Quaternary deposits overlying the Tertiary beds.

This report presents the above-mentioned information for the project area.

Additional studies in the south-Arkansas lignite area will use the information presented in this report as indicators of the kinds of additional data needed to further define the hydrology in the area and as part of the input to a digital model which will be used to predict the impacts of mining upon the ground-water regime.

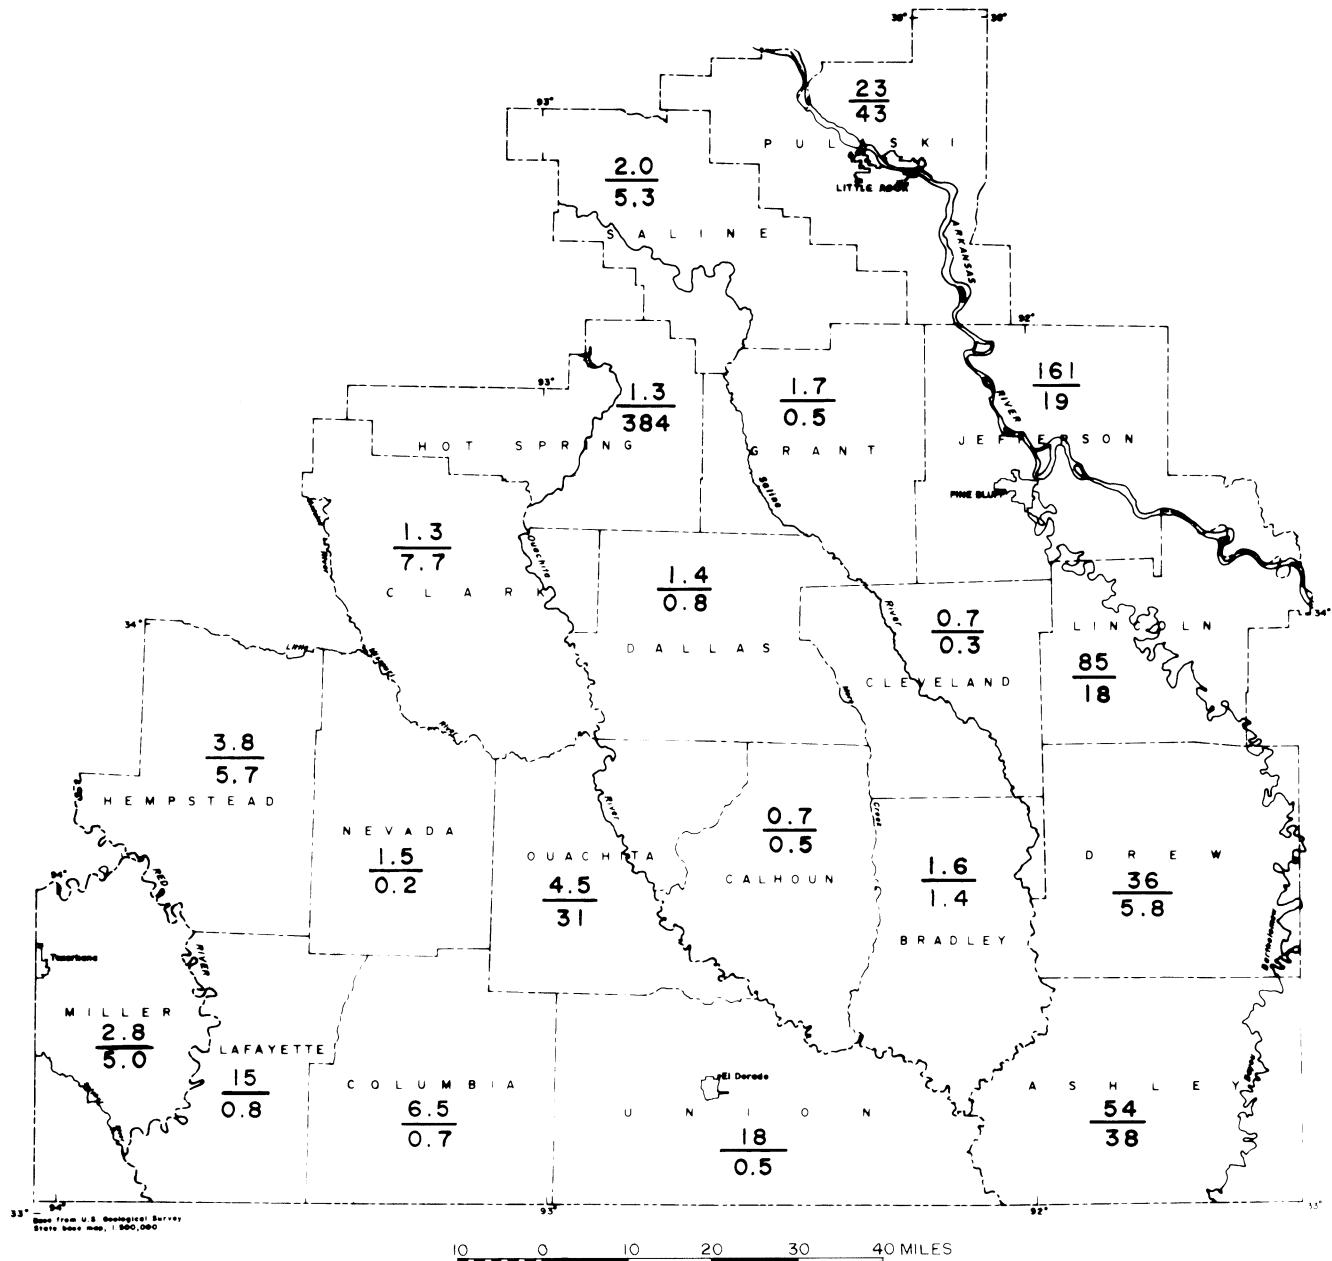

Previous Investigations

Many reports cover one or several facets of the water resources of part or all of the lignite area of south Arkansas. Reports dealing with surface water include reports on low flow (Hines, 1975), storage requirements (Patterson, 1967), and floods (Patterson, 1971). Ground-water investigations encompassing all of the south-Arkansas lignite area include reports on the aquifers of Tertiary age (Hosman and others, 1968), aquifers of Quaternary age (Boswell and others, 1968), aquifers of Cretaceous age (Boswell and others, 1965), and the base of freshwater (Cushing, 1966). Areal ground-water investigations within the project area include reports covering Ashley County (Hewitt and others, 1949), Bradley, Calhoun, and Ouachita Counties (Albin, 1964). Columbia County (Tait and others, 1953), Drew County (Onellion, 1956), the El Dorado area in Union County (Baker and others, 1948), Jefferson County (Klein and others, 1950), and Lincoln County (Bedinger and Reed, 1961). Water-resources investigations of areas within the project area include reports covering Clark, Cleveland, and Dallas Counties (Plebuch and Hines, 1969), Grant and Hot Spring Counties (Halberg and others, 1968), Hempstead, Lafayette, Little River, Miller, and Nevada Counties (Ludwig, 1972), and Pulaski and Saline Counties (Plebuch and Hines, 1967).

APPRAISAL OF THE WATER RESOURCES

Water Use

In 1975, the combined use of ground water and surface water in the 20 counties containing the project area was 991 Mgal/d (Halberg, 1977). Surface-water use was 569 Mgal/d and ground-water use was 422 Mgal/d. The use of ground water and surface water for 1975 for each of the counties is shown in figure 2. Of the surface-water use, 70 percent was for cooling at thermo-electric powerplants. Substantial amounts of surface water were used for public supply, self-supplied industry, irrigation, and fish farms. The largest use of surface water (384 Mgal/d) was in Hot Spring County, and the smallest use (0.2 Mgal/d) was in Nevada County (table 1). Most of the ground-water use (table 2) was from the deposits of Quaternary age (312 Mgal/d) and from the Sparta Sand (92 Mgal/d).

Surface Water

The largest source of surface water in the project area is the Red River, which had an average flow at Fulton of $17,730 \text{ ft}^3/\text{s}$ for the period 1927-76. The Ouachita River at Camden, where it has a drainage area of $5,391 \text{ mi}^2$, had an average flow of $7,562 \text{ ft}^3/\text{s}$ for the period 1928-75. These and other mean flows for several streams in the lignite area are shown in table 3. Downstream, at the Arkansas-Louisiana State boundary, where the Ouachita River's drainage area is $10,835 \text{ mi}^2$, it has an estimated average flow of about $14,800 \text{ ft}^3/\text{s}$. The average flow in a stream is related to its drainage area. The relationship between average annual streamflow and drainage area for streams in Arkansas has been shown in map form by Patterson (1967, fig. 15). The part of his map that includes the lignite project area is shown in figure 3. The range for the lignite area is from $(0.9 \text{ ft}^3/\text{s})/\text{mi}^2$ to $(1.3 \text{ ft}^3/\text{s})/\text{mi}^2$.

Flow Duration

Flow-duration data, as shown in table 4, for regular-gaging stations in the project area indicate for a particular stream the discharge that is equaled or exceeded for a given percentage of time. Flow duration ignores the characteristics of individual events but combines all events into one relationship for the stream. If the period for which the flow-duration data were collected is representative, the flow-duration relationship should apply in the future as long as hydrologic conditions do not change. Regulation of streamflow usually changes the flow-duration relationship. Some of the stations shown in table 4 have flow-duration data for both preregulated and regulated flow. Variation in flow, as reflected in flow duration, is a function of climate and the hydrologic characteristics of the drainage basin. Regulation of flow

by reservoirs reduces flow variation. Flow-duration relationships at each station were defined by the percentage of time, during the period of record, that the daily mean flow was greater than a specified value. "The daily mean flow values for the period of record at each gaging station were sorted by computer into about 30 classes. Each class represents a range in daily-mean flow. These classes include the highest and lowest daily flows and are uniformly distributed throughout the range of daily flow. Each daily-mean flow for the period of record was included in its appropriate class. The number of days thus represented in each class were accumulated, beginning at the highest daily-mean flow class, and the percentage of days when the flow was greater than the lower limit of each class in the accumulation was computed" (Hines, 1975). Flow duration is a cumulative frequency obtained by summing the class frequencies beginning with the class of highest flow.

Flow duration was estimated at low-flow partial-record stations and the estimated flows at 99- and 90-percent duration are shown in table 5. These flows were estimated by correlation with flows at continuous-record gaging stations. They are not as accurate as data for continuous-record stations but do indicate hydrologic conditions existing at partial-record sites.

Flow-duration data can be plotted on logarithmic-probability paper if a graphical presentation is desired. The slope of the duration curve reflects variations in flow caused by the hydrologic and geologic characteristics of the river basin upstream from the station. The slopes of the curves for streams that have large low-flow yields are flatter than those for streams that have small low-flow yields. Thus, the flow-duration data are useful for comparing the flow characteristics of different streams.

Low-Flow Frequency

Low-flow frequency for regular-gaging stations was computed from annual events occurring during the period of record. The events were the

lowest mean discharges for 1-, 7-, 14-, 30-, 60-, and 120-day periods during each year. The recurrence interval for these events was determined by either fitting a mathematical-frequency distribution to the data or by plotting the data on a graph and drawing a smooth curve through the data points (Hines, 1975). The resulting annual low flows for given recurrence intervals are shown in table 6 for streams in the project area.

Estimates of low-flow characteristics at partial-record stations were made by comparing measurements of low flow at the partial-record station with concurrent daily-mean discharge at a continuous-record gaging station. These continuous- and partial-record gaging stations are shown in figure 4. The criteria for selecting a continuous-record station for comparison were that it should have a long-term record, be near the partial-record station, and reflect similar hydrologic conditions as the partial-record station. If a curve relating discharge at the two stations could be found, estimates of low flow at the partial-record station could be made based on corresponding frequency values, at the continuous-record station. Estimates of low-flow frequency obtained by the preceding method, for partial-record stations in the lignite area, are shown in table 5.

Low-flow frequency is important in determining the water-supply potential at a given site on a stream. Draft rates in excess of expected low flow must be supplied from storage. Storage requirements for streams in the lignite area are included in a report by Patterson (1967). Another use for low-flow data is in determining the waste-assimilation capacity of streams, such as the study by Jennings and Bryant (1974).

Many streams in south Arkansas would be classified as not having sustained base flow (Hines, 1975, fig. 7). The only part of the project area where streams have sustained base flow is the drainage of the Ouachita River upstream from Camden (Hines, 1975, fig. 7).

Flood Frequency

Flood frequency is often used as an indicator of the use that could be made of the flood plains of streams, the design characteristics of structures that must occupy the flood plain, and flood-insurance rates for developed areas of flood plains. The best method, at present, for estimating future flood events is by the analyses of past flood events. Flood frequency at points on a stream is determined from annual peak events for the period of record. The annual flood is the highest instantaneous discharge that has occurred during a year of record. A recurrence interval is determined from these annual floods, either by fitting them to a frequency distribution or by plotting the flood-data points and drawing a smooth curve through them.

An analysis of floods in Arkansas was made by Patterson (1971). His report (p. 3) has a description of methods for determining recurrence interval from gaging-station records by either the log-Pearson Type III frequency distribution or by graphical methods. Characteristics of annual floods, as determined by Patterson (1971), for sites in the project area are given in table 7.

The results of frequency analysis for gaging stations were expanded to include ungaged sites through the use of regression analysis (Patterson, 1971). Patterson related annual peak flow to hydrologic characteristics of the streams. Significant characteristics were found to be drainage area, main-channel slope, annual precipitation, and mean basin elevation for streams within the lignite area. Patterson's equations are given in table 8 for the parts of Arkansas that include the lignite area. The simplest equations require only information on the drainage area upstream from the site. However, the equation relating peak flow to drainage area also has the largest standard error. Better estimates of peak flow require more information on characteristics of the drainage basin. If increased accuracy is desired, one or more equation variables, in addition to drainage area, must be defined.

Table 7.—Characteristics of annual floods for gaging stations in the project area

[Type: P, partial-record station; D, continuous-record gaging station. Modified from Patterson, 1978]

Number	Type	Name	Peak discharge, in cubic feet per second, for indicated recurrence interval, in years

(d)	Q_{50}	3,620	.46	----	----	----	41	--

*Not applicable for drainage areas less than 25 mi².

For small drainage areas, generally less than 25 mi², frequency relations are not defined for recurrence intervals of more than 10 years. Therefore, for drainage areas of this size, equations 12 and 13 in table 8 are invalid and should not be used. Patterson developed a method for estimating the Q₂₅ and Q₅₀ for drainage areas less than 25 mi². He determined values for the ratios Q₂₅/Q₁₀ and Q₅₀/Q₁₀ for long-term gaging stations throughout the State. These values were then related to basin parameters and a reasonably good correlation was obtained using main-channel slope as an independent variable. The relation curves shown in figure 5 reflect the results of this analysis. Peak flows for recurrence intervals of 25 and 50 years for small drainage areas in the project area can be estimated by first determining the 10-year flood and then multiplying by the appropriate value from the relation curves in figure 5.

Flood Stage

The elevation of the water surface, as well as the discharge, is important for planning purposes in the construction of structures or earthworks in the vicinity of streams. Methods requiring extensive field surveys are available to accurately determine the elevation and peak flow of design floods and should be used if extreme accuracy is required. However, the following procedure may be used in the absence, or in support, of other streamflow data to obtain an approximation of the elevation of the 50-year flood for any gaged or ungaged sites on streams in the project area. The procedure developed by Hines (1977) enables the determination of the elevation of the 50-year flood using a stage increment (ΔD) representing the surcharge produced by the 50-year flood discharge over the 50-percent-duration (median) flow.

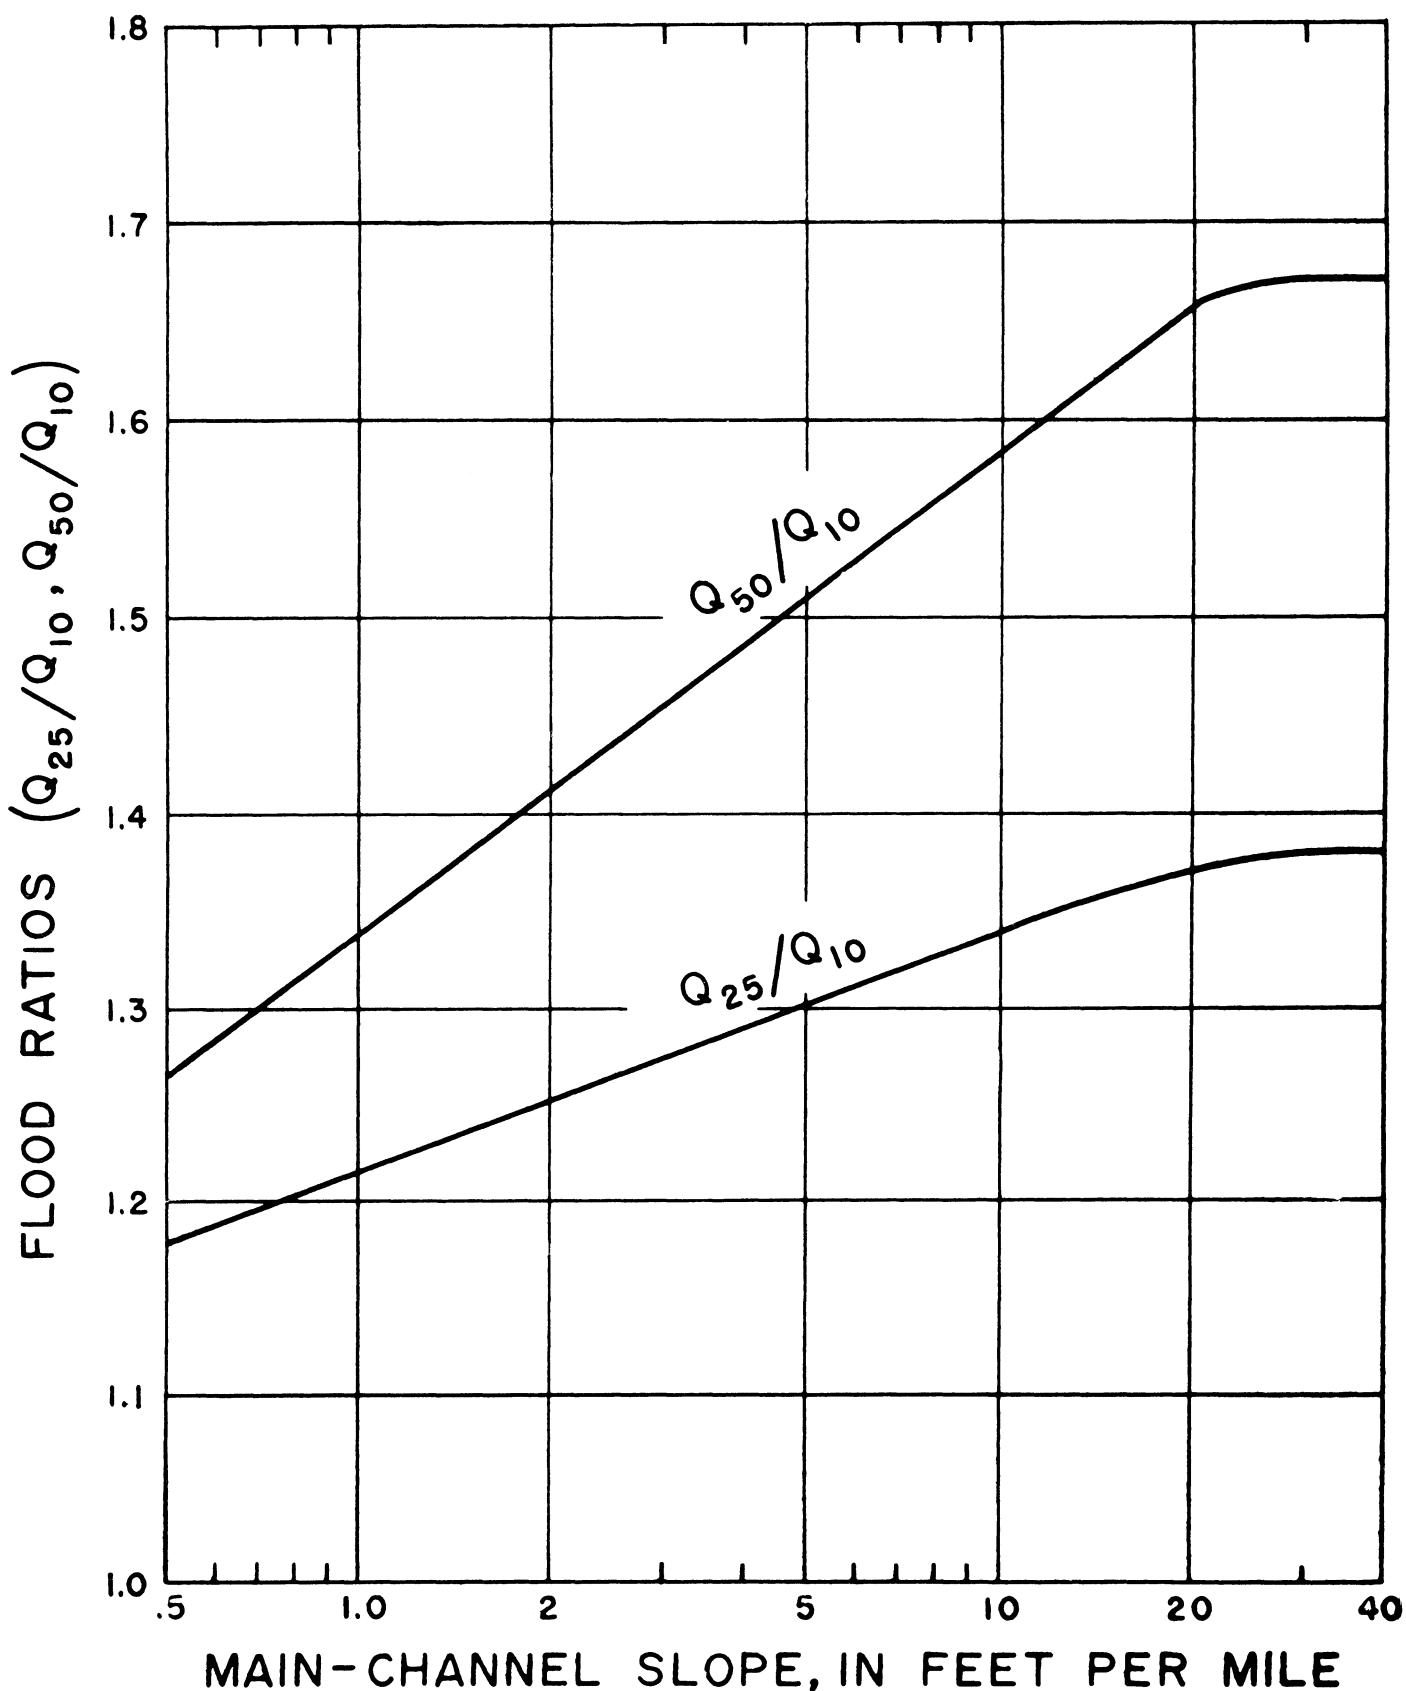

Figure 5.—Relation between flood ratios and main-channel slope.

For the project area, the increment of stage (ΔD) applicable to drainage areas of from 80 to 1,000 mi² is shown in figure 6. To use the graph, it is first necessary to determine the elevation of the median flow, either from topographic maps or from field observations, and second to add the ΔD value for the particular drainage area from the graph to that elevation. A reasonable assumption is that the contour "turnbacks" on streams (where the contour lines cross the streams) are at the elevation of the median flow.

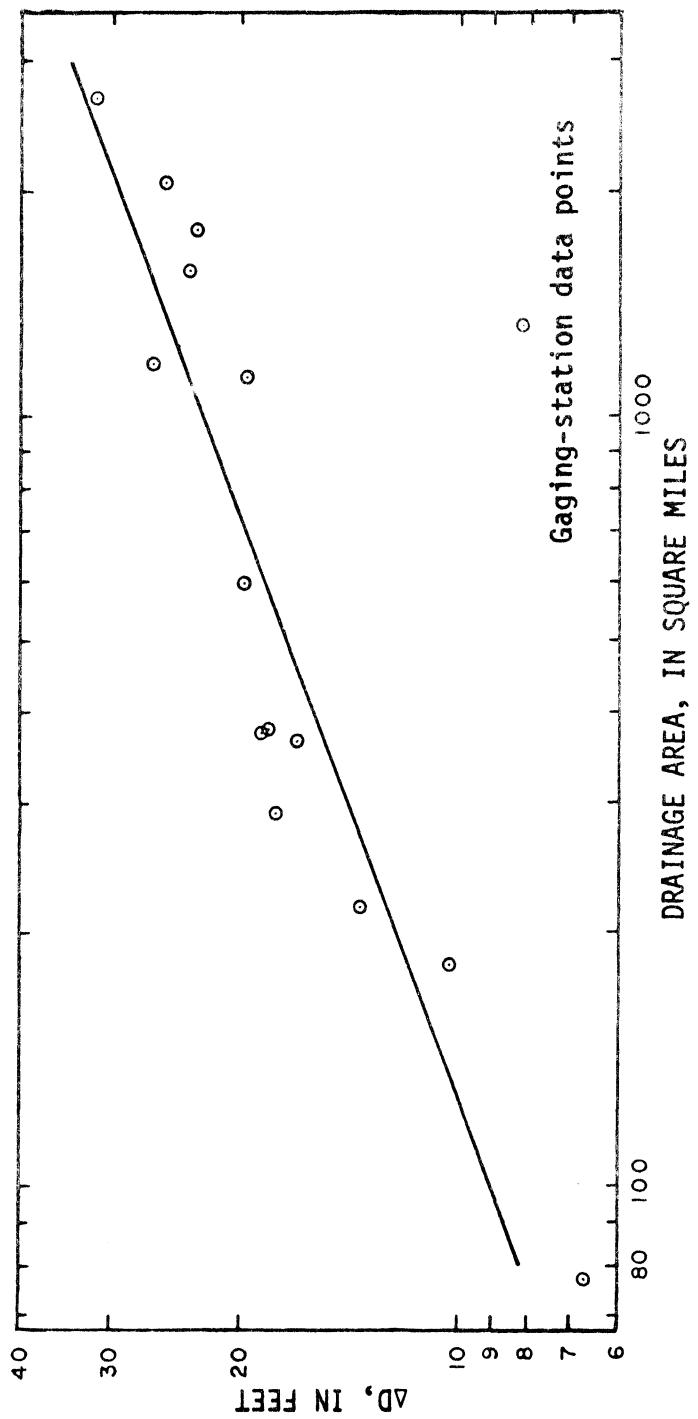

Figure 6.—Elevation of 50-year floodflow minus elevation of 50-percent duration flow (ΔD) versus drainage area for the project area (from Hines, 1977).

Quality of Surface Water

One of the concerns of large-scale strip mining is the potential degradation of environmental quality, especially surface-water quality. A part of this study is to determine water-quality conditions of streams in the south-central Arkansas lignite area prior to mining activities.

To determine background (present) water quality, data for a number of stations, which are located on selected streams in the study area, were evaluated (fig. 7). The data were collected by the Arkansas Department of Pollution Control and Ecology and by the U.S. Geological Survey in cooperation with the Arkansas Geological Commission. A few of the stations are inactive.

The results of statistical analysis of selected water-quality parameters for these stations are presented in tabular form. The results are for a period of 2 or more years and are based on data collected between 1967 and 1977.

In addition to current and historic water-quality stations, a number of sampling sites have been established downstream from probable mining areas (fig. 7). These sites include: 07348590, Bayou Dorcheat near Falcon; 07349415, Little Bodcau Creek at Bodcau; 07360161, Cypress Creek near Sparkman; 07360182, Brushy Creek near Ouachita; 07361650, Terre Rouge Creek near Prescott; 07361660, Little Missouri River near Whelen Springs; 07361700, Caney Creek near Bluff City; 07361805, Terre Noire Creek at Vaden; 07361850, Tulip Creek near Pine Grove; and 07364035, L'Aigle Creek near Ingalls.

In addition, water-quality stations 07363300, Hurricane Creek near Sheridan, and 07363500, Saline River near Rye, have been reactivated for this study.

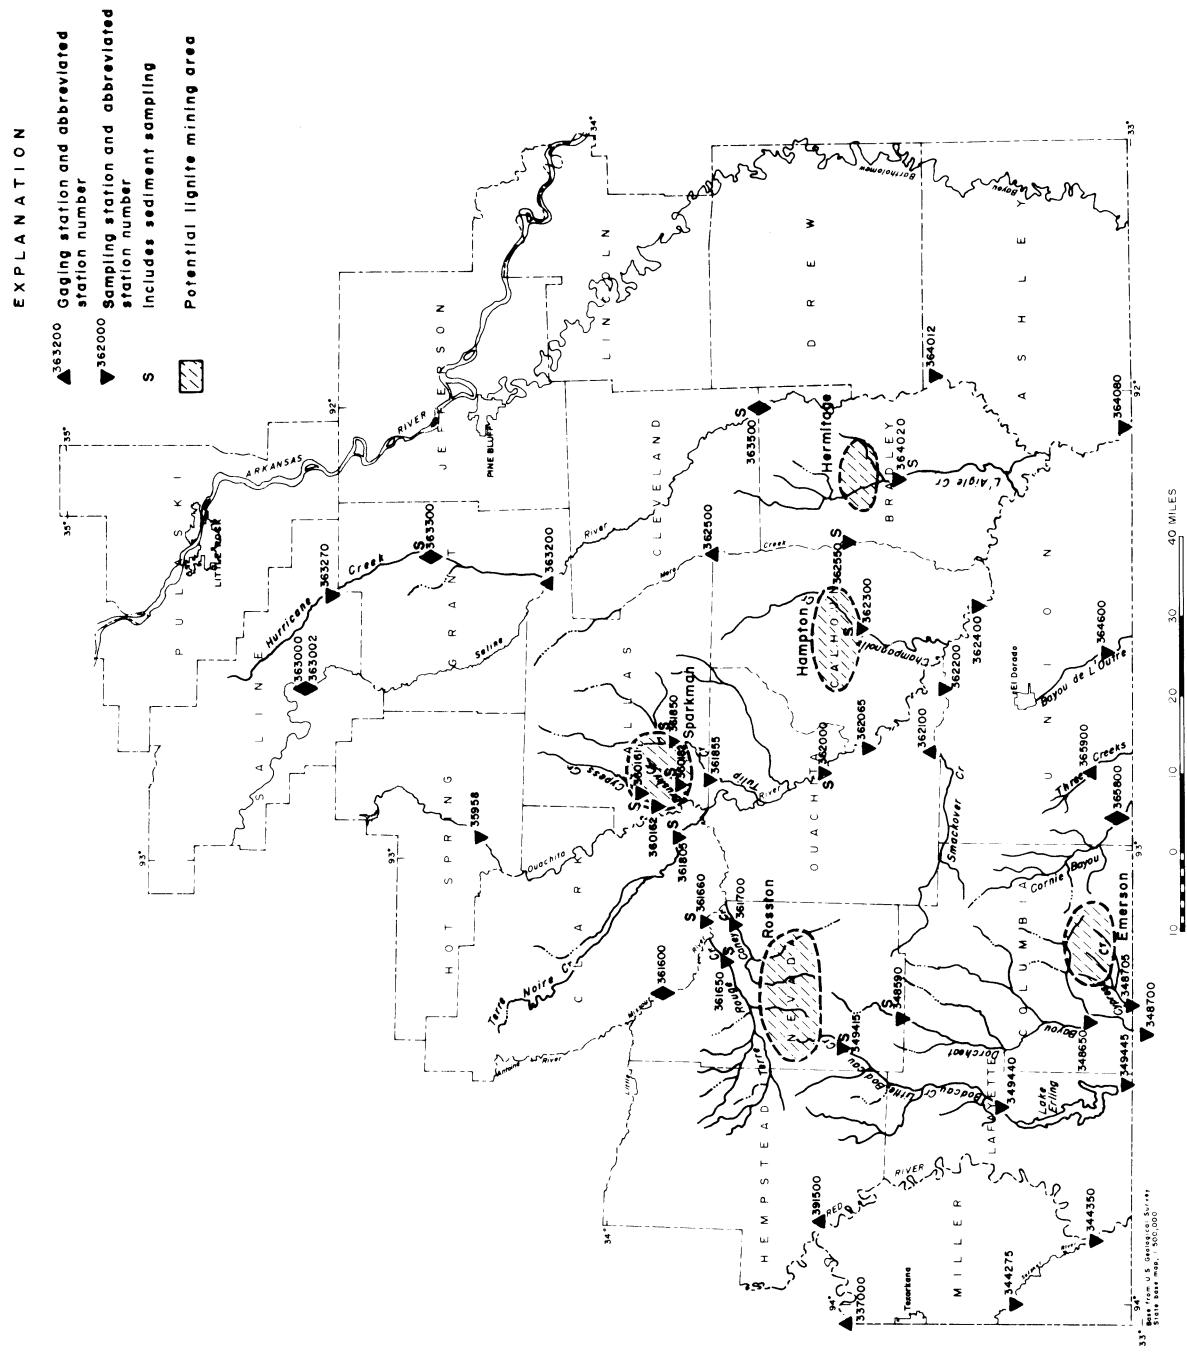

Figure 7.- Water-quality data-collection network in the project area.

Samples collected at all water-quality stations are analyzed for the common ions, organic carbon, suspended sediment, trace metals, dissolved oxygen, temperature, pH, conductivity, and benthic organisms. Organic carbon, sediment data, and benthic organisms are also being collected at continuous-record stream-gaging stations 07359500, Ouachita River near Malvern, and 07362550, Moro Creek near Banks.

Samples collected by the Geological Survey were analyzed using the techniques given in Brown, Skovstad, and Fishman (1970). Analytical procedures used by the Arkansas Department of Pollution Control and Ecology include methods published by the American Public Health Association (1976), the American Society for Testing and Materials (1974), and the U.S. Environmental Protection Agency (1974).

Red River

Two water-quality sampling stations operated by the Arkansas Department of Pollution Control and Ecology are located on the Red River in Arkansas. One station, 07336860, is located near where the river enters Arkansas and the other station, 07344350, near where the river leaves Arkansas (fig. 7). Statistical summaries for these stations are shown in tables 9 and 10. The Red River is characterized by a very high concentration of suspended sediment, as evidenced by excessive turbidity concentrations and total nonfilterable residue (the suspended matter that will not pass through a 0.75-1.25 micrometer glass fiber filter) (table 9). Turbidity concentrations at times exceed the Arkansas State standard of 50 Jtu (Jackson turbidity unit). The annual sediment load of the Red River at a long-term monitoring station at Index, Ark., averages 520 tons per square mile of drainage area (U.S. Army Corps of Engineers, New Orleans District, 1966, p. I-23). Most of the sediment originates in the upper Red River basin where red, sandy soils are predominant and are subject to erosion. The iron-bearing, red soil probably accounts for the high total iron concentrations shown in table 9.

Table 9.—Water-quality statistical summary for station 07336860, Red River near Foreman, Ark.

The stream is further characterized by the predominance of sodium, bicarbonate, sulfate, and chloride ions. These ions decrease in concentration from the upstream station (07336860) to the downstream station (07344350), probably due to dilution from tributaries between the stations. Chloride concentrations in the Red River sometimes exceed the U.S. Public Health Service standard of 250 mg/L (milligrams per liter) for drinking water (table 11).

Sulphur River

A sampling station on the Sulphur River (07344275) has been operated by the Arkansas Department of Pollution Control and Ecology since 1968. Water in the Sulphur River is a calcium bicarbonate type and occasionally contains high concentrations of iron (table 12) which often exceed U.S. Public Health Service standards. The stream is overloaded with wastes from municipal and industrial discharges resulting in dissolved-oxygen concentrations often in violation of the Arkansas standard of 5.0 mg/L (table 11).

Bayou Dorcheat

Statistical data are presented for two sampling stations on Bayou Dorcheat (tables 13 and 14). The stations are operated by the Arkansas Department of Pollution Control and Ecology. The station near Taylor (07348650) has been operated since April 1974. The other station (07348700) 10 mi downstream and located near Springhill, La., was operated from March 1968 to September 1974. Bayou Dorcheat receives municipal and industrial wastes through some of its tributaries and also receives some impact on its quality from oil-field brines (Arkansas Department of Pollution Control and Ecology, 1973, 1975).

Table 11.—Water-quality standards and recommended water-quality limits

¹Standards are based on 96-hour Median Tolerance Limit. See "Arkansas Water Quality Standards, Regulation No. 2, as Amended," September 1975.

²Standards are set for individual streams. See "Arkansas Water-Quality Standards, Regulation No. 2, as Amended," September 1975.

³Hexavalent (Cr^{+6}).

⁴Minimum of 5.0 mg/L, except for natural conditions.

Minimum of 6.0 mg/L for trout and small-mouth bass streams.

⁵For trout or small-mouth bass streams, the standard is 10 JTU.

Water in Bayou Dorcheat, at the upstream site near Taylor, 07348650, does not meet State water-quality standards (table 11). Dissolved oxygen concentrations are often less than the minimum recommended 5.0 mg/L. Iron and manganese concentrations are generally high at this location and exceed recommended maximums for drinking water. Lead concentration, at times, also exceeds standards.

Data for the downstream site near Springhill, 07348700, show some additional degradation in quality occurring between the two sites. For example, the average chloride concentration increased almost fourfold, probably because of oil-field brines.

No sediment data are available for this stream. Benthic organisms were collected at the station near Taylor, 07348650, in 1973, and the findings were published by the Arkansas Department of Pollution Control and Ecology (1976). A good benthic population was found.

Cypress Creek

Cypress Creek is a tributary to Bayou Dorcheat and drains a potential mining area in the vicinity of Emerson. A water-quality station, 07348705, was operated by the Arkansas Department of Pollution Control and Ecology at the Arkansas-Louisiana State line from March 1968 to April 1974. This stream is in a low, marshy area and has infrequent flow and low velocity, that makes it difficult to interpret its water quality. Chromium, lead, iron, and manganese concentrations have exceeded water-quality standards (table 15). In 17 samples, the maximum chloride concentration was 1,330 mg/L which indicates oil-field pollution. The dissolved-oxygen concentration has been less than the State's standard of 5.0 mg/L. No benthic or sediment data are available for this stream.

Bodcau Creek

Statistical data are presented for two stations on Bodcau Creek (tables 16 and 17). The station near Lewisville (07349440) drains a low, marshy area resulting in a summertime stratification of the water. Dissolved-oxygen concentrations range from 0.0 mg/L near the bottom of the stream to 5.0 mg/L near the surface.

As with other streams in the area, iron, manganese, and lead concentrations are high at times, exceeding standards for drinking water (table 16). In 1973, upstream from this station and 5 miles downstream from where the Stamps sewage-treatment plant effluent enters the stream, the Arkansas Department of Pollution Control and Ecology found a good benthic community in the stream with a diversity index of 2.5947, an indication that the stream is in good condition, with the exceptions noted previously.

The station near Taylor (07349445) is downstream from Lake Erling, and water quality at this site shows some improvement after the water moves through the lake. The dissolved-oxygen concentration remains above 5.0 mg/L (table 17). Iron concentration is less, but lead and manganese concentrations are a little higher than concentrations upstream from the lake. Chromium concentration is noticeably higher downstream from Lake Erling and exceeds drinking-water standards. The source of the chromium is not known.

No recent benthic sampling has been done at either site. However, as mentioned above, in 1973, a good benthic population was found 5 miles downstream from where the Stamps waste effluent enters the stream. No sediment data are available for Bodcau Creek.

Ouachita River

Statistical data are presented for seven water-quality sampling sites on the Ouachita River (tables 18 through 24). These sites are: Station 07359500,

near Malvern, upstream from potential mining areas; station 07359580, near Donaldson; station 07360162, near Sparkman; station 07362000, at Camden and downstream from the confluence of the Little Missouri River; station 07362065, "below" Camden; station 07362400 at Lock and Dam 8, near Calion, and downstream from the confluence of Smackover Creek; and station 07364080, near Felsenthal and near the Arkansas-Louisiana State boundary, downstream from the confluences of Moro Creek and the Saline River.

The stations "at" and "below" Camden, 07362000, and 07362065, are U.S. Geological Survey stations. The station "below" Camden (07362065) is inactive. The rest of the stations on the Ouachita River are operated by the Arkansas Department of Pollution Control and Ecology.

Water quality of the Ouachita River at the three upstream stations near Malvern, Donaldson, and Sparkman is similar. However, there is an increase in iron and lead concentrations from the station near Malvern (07359500) to the station near Sparkman (07360162). Iron, lead, and manganese concentrations at all stations on the Ouachita River sometimes exceed standards for drinking water. The sources of these metals may be the mining activities near Hot Springs.

Data for stations on the Ouachita River at and downstream from Camden show some dilutional effect of the Little Missouri River whose confluence is several miles upstream from these stations. Most noticeable are reductions in specific conductance, sulfate, and chloride.

The station at Lock and Dam 8 near Calion (07362400), reflects the influence of Smackover Creek (table 23). Of particular note are increases in specific conductance, sodium, chloride, and total filterable residue (see discussion of Smackover Creek). Those same parameters continue to increase, as shown by data for the station near Felsenthal, despite some dilution by Moro Creek and Saline River. Like Smackover Creek, the lower part of the Ouachita River receives oil-field brines high in sodium chloride.

The Ouachita River shows a general deterioration in quality from the station near Malvern (07359500) to the Arkansas-Louisiana State line. Some of the deterioration results from mining activities upstream from the study area. In addition, there is a large number of municipal and industrial waste discharges, both on the main stem of the Ouachita River and on a number of tributary streams (Arkansas Department of Pollution Control and Ecology, 1977). As a result of these wastes, dissolved-oxygen concentrations are sometimes suppressed to less than the State standard of 5.0 mg/L. The Ouachita River water quality is further deteriorated downstream from Smackover Creek which carries oil-field brines into the river.

No benthic or sediment data are published for the Ouachita River. However, benthic and sediment data are being collected at the stations near Malvern and at Camden and will be published in a subsequent report.

Little Missouri River

The Arkansas Department of Pollution Control and Ecology has operated a sampling station on the Little Missouri River near Boughton (07361600) since April 1974. Statistical data for this station (table 25) show the stream to be of good quality except for occasional high concentrations of iron, lead, manganese, and unfilterable residues.

There are no waste sources directly on the main stem of the river, but a few effluents are located on tributary streams (Arkansas Department of Pollution Control and Ecology, 1977).

Benthic and sediment data are not available at this site. Both types of data are being collected at station 07361660, near Whelen Springs, and will be published in a subsequent report.

Table 25.—Water-quality statistical summary for station 07361500, Little Missouri River near Broughton, Ark.

Smackover Creek

Data are given for two stations on Smackover Creek (tables 26 and 27). Station 07362110, north of Smackover, Ark., has been operated by the Arkansas Department of Pollution Control and Ecology since April 1974. The other station, 07362200, was operated by the Geological Survey from 1959 to 1972. Water in Smackover Creek is of very poor quality. A number of refineries, chemical plants, and municipalities discharge their waste water into Smackover Creek or into one of its tributaries. In addition, oil-field brines are flushed into the creek during surface runoff. The results of these wastes can be seen in the high concentrations of sodium, chloride, dissolved solids, and total filterable residue.

Benthic data were collected at several locations on Smackover Creek during summer surveys in 1974 and 1975 by the Arkansas Department of Pollution Control and Ecology (1977). Population densities of benthic organisms generally decreased downstream. No sediment data are available for this stream.

Moro Creek

Data for one station near Banks (07362550) are given in table 28. This station has been operated by the Arkansas Department of Pollution Control and Ecology since April 1974. Like most streams in the study area, high concentrations of iron, lead, and manganese are present which sometimes exceed standards (table 11). This stream usually does not flow during late summer and fall. When streamflow becomes low, dissolved oxygen is sometimes reduced to less than 5.0 mg/L.

No waste sources are discharged directly into Moro Creek, but three municipal and two industrial waste sources discharge into tributaries of Moro

Creek (Arkansas Department of Pollution Control and Ecology, 1970). Probable cause of low dissolved-oxygen concentration in the stream is forest litter in combination with low velocities.

Benthic organisms were collected in 1974 and 1975 at two locations upstream from the station near Banks (07362550), in the vicinity of Fordyce, by the Arkansas Department of Pollution Control and Ecology (1977). Sediment data are being collected at the station near Banks but are not available for publication.

Saline River

Data are given for four stations on the Saline River (tables 29 through 32). Two of these, operated by the Arkansas Department of Pollution Control and Ecology, are 07363002, west of Benton, and 07364012, near Fountain Hill (fig. 7). The other two stations, 07363080, near Tull, and 07363500, near Rye, were operated by the Geological Survey. The station near Rye has been reactivated for the present study.

The Saline River water is of good quality except for certain trace metals, which at times exceed levels recommended for drinking water. Metals exceeding recommended limits include copper, iron, lead, manganese, and zinc (tables 29 through 32).

No sediment or benthic data are available for publication, but both are being collected at station 07363500, near Rye. These data will be published in a subsequent report.

Hurricane Creek

Hurricane Creek is a tributary to the Saline River (fig. 7) and drains an area of bauxite mining. The Arkansas Department of Pollution Control and

Ecology has operated a water-quality station (07363270) near Sardis since 1974. The Geological Survey operated a water-quality station (07363300) near Sheridan from October 1949 to September 1954 and from October 1967 to September 1972. This station has been reactivated for this study.

As might be expected of a stream draining a mining area, high concentrations of some trace metals have been reported (tables 33 and 34). Metals in excess of recommended limits include cadmium, iron, lead, and manganese. Sulfates sometime exceed standards (table 33).

No sediment and benthic data are available for publication. However, both sediment and benthic data are being collected at the station near Sheridan. Early indications are that benthic communities are very small (E.E. Morris, oral commun., 1978), probably as a result of upstream mining activities. Both sediment and benthic data will be published in a subsequent report.

Bayou de Loutre

Statistical data are given for a water-quality station (07364600) on Bayou de Loutre near El Dorado (table 35). The station has been operated by the Arkansas Department of Pollution Control and Ecology since October 1970. This stream drains an area of oil-field activities, and the water quality of the stream reflects those activities. High chloride concentrations resulting from oil-field brines exceed limits for human consumption. Of metals present, chromium, iron, lead, and manganese exceed limits. Dissolved oxygen is sometimes less than the State standard of 5.0 mg/L, probably as a result of low flows, municipal and industrial wastes (Arkansas Department of Pollution Control and Ecology, 1975), respiration of aquatic plants, and oxygen demand of the breakdown of organic detritus from forest litter. No sediment or benthic data are available for this stream.

Table 33.—Water-quality statistical summary for station 07363270, Hurricane Creek near Sardis, Ark.

Cornie Bayou

Station 07365800 (fig. 7), Cornie Bayou near the town of Three Creeks, was operated by the Arkansas Department of Pollution Control and Ecology from February 1968 to April 1974. Table 36 gives the statistical data for this station. Part of the drainage area of this stream is comprised of oil fields and is subject to degradation by oil-field wastes. Data for station 07365800 reflect some degradation from oil fields. The maximum chloride concentration of 240 mg/L (table 36), which is near the recommended maximum allowed for drinking water, probably resulted from oil-field brine. Arsenic, chromium, iron, lead, and manganese concentrations have exceeded standards. Dissolved-oxygen concentration is sometimes less than the 5.0 mg/L minimum recommended by State water-quality standards. No benthic or sediment data are available for this stream.

Three Creeks

Table 37 gives statistical data for a water-quality station (07365900), on Three Creeks, near the town of Three Creeks. This station was operated by the Arkansas Department of Pollution Control and Ecology from February 1968 to April 1974, and data show the stream to be degraded by oil-field wastes (Arkansas Department of Pollution Control and Ecology, 1975). However, two samples collected during the summer of 1974, at the Arkansas-Louisiana State boundary, indicate some improvement in water quality (Arkansas Department of Pollution Control and Ecology, 1975).

At the station near Three Creeks, dissolved oxygen, chloride, chromium, iron, lead, manganese, and zinc concentrations (table 37) are in violation of one or more of the standards shown in table 11.

A varied benthic community was reported for this stream at the Arkansas-Louisiana State boundary for the summer of 1974 (Arkansas Department of Pollution Control and Ecology, 1975). No sediment data are available.

Table 36.—Water-quality statistical summary for station 07365800, Cornie Bayou near Three Creeks, Ark.

Ground-Water Occurrence and Quality

The geologic column in south Arkansas is summarized in table 38. Lignite occurs in Tertiary deposits of Eocene age. "Arkansas lignite is found principally in strata of Eocene age. It is most abundant in strata of the Wilcox Group and successively less abundant in the overlying Claiborne and Jackson Groups" (Stroud and others, 1969). The Eocene deposits also contain aquifers that are important sources of water supply both locally and regionally. Total ground-water usage in the study area was 422 Mgal/d in 1975 (Halberg, 1975).

Much of the definition of the geologic units in the subsurface is based on interpretation of electric logs of test holes drilled for oil and gas exploration. An example of such an electric log is shown in figure 8. The geologic units have been correlated throughout the Coastal Plain of Arkansas and in parts of adjacent States in regional hydrologic studies such as U.S. Geological Survey Professional Papers 448 and 569.

The stratigraphic relationships of the Tertiary units in the project area are shown by five geologic cross sections located as shown in figure 9. The cross sections are shown in figure 10, sheets 1 through 4. Table 39 contains information on the test holes and wells used to define the cross sections.

Most of the aquifers that yield freshwater in the study area are part of, or lie above, the Eocene Series. The exceptions are the Clayton Formation of Paleocene age and the Nacatoch Sand of Cretaceous age. These two aquifers yield freshwater within small areas in the project area. The geologic units below the Nacatoch Sand do not contain freshwater in the project area.

Table 38.—Generalized geologic column in the lignite area of southern Arkansas

System	Series	Group	Formation	Lignite occurrence
Quaternary	Holocene		Terrace and stream deposits	Lignite beds absent
	Pleistocene	Jackson	Undifferentiated

A network of 600 observation wells has been established in the project area. Water-level measurements will be made in these wells biannually. Spring (1978) measurements have been made, and were used in defining the potentiometric surfaces for the Cockfield Formation, Sparta Sand, Cane River Formation, and the Carrizo Sand. Additional observation wells are being added, when possible, to the existing network.

Nacatoch Sand

The Nacatoch Sand is present in the subsurface throughout most of the project area (fig. 11). However, it contains freshwater in only a small area near its outcrop. This area includes parts of Miller, Hempstead, Nevada, and Clark Counties. The Nacatoch Sand consists mostly of sand and calcareous clay. In the subsurface, adjacent to its outcrop in southwest Arkansas (Boswell and others, 1965), the Nacatoch Sand is from about 150 ft to more than 500 ft thick and the percentage of sand is from less than 20 to as much as 80 (fig. 12). Most of the sandy material is in the upper part of the formation. The sandy upper part of the formation is an aquifer that furnishes as much as 300 gal/min to wells in or near the outcrop. The potentiometric surface (altitude to which water will rise in wells tapping a confined artesian aquifer) for the Nacatoch Sand is shown in figure 13. The general movement of water in the formation is southeastward.

The quality of water from the Nacatoch Sand is generally poor in the project area. Throughout most of the south-Arkansas lignite area, the Nacatoch Sand does not contain freshwater (Cushing, 1966). Only in parts of Miller, Hempstead, Nevada, and Clark Counties does the Nacatoch Sand contain water having less than 1,000 mg/L of dissolved solids. The average specific conductance, as determined from 72 analyses (table 40), is about $1,900 \text{ (cm}^{-1}\text{ at } 25^\circ\text{C)} \mu\text{mho}$ with values ranging from 190 to $19,900 \mu\text{mho}$. The pH values range from 7.4 to 9.0.

and average 8.5. In Clark County, water from the Nacatoch Sand is hard in many places. For the 18 analyses shown in table 40, the maximum values of hardness, as calcium carbonate (CaCO_3), is 2,690 mg/L, with most values ranging between 18 and 154 mg/L. Water from the Nacatoch in Nevada County is soft, averaging 9.4 mg/L CaCO_3 for 14 samples. The average hardness is 46 mg/L CaCO_3 in 15 samples from Hempstead County and 53 mg/L in 26 samples from Miller County. Overlying the Nacatoch Sand is the Arkadelphia Marl, which is in turn overlain by the Midway Group. The Arkadelphia Marl consists of calcareous clay and limestone and ranges from 0 to 150 ft thick. The formation contains practically no sand beds and is not an aquifer in the project area.

Midway Group

The Midway Group in the project area consists of calcareous clay, sandy limestone, and calcareous sandstone and is from about 400 to 600 ft thick in the subsurface. A structural contour map of the top of the Midway is shown in figure 14. The amount of sand in the Midway ranges from 0 to about 20 percent. The calcareous sandstone and limestone at the base of the Midway Group make up the Clayton Formation, which is an aquifer in the northern part of the project area. In some places there is appreciable sand in the Clayton Formation. The Clayton Formation (Kincaid Formation in the Arkansas bauxite area) is generally about 35 ft thick and furnishes as much as 350 gal/min to wells near its outcrop in Hot Spring, Saline, and Pulaski Counties. The upper part of the Midway Group, the Porters Creek Clay (Wills Point Formation in the Bauxite area), is not an aquifer in the project area.

The only information available at the present time on the chemical quality of water from the Clayton Formation in the project area is from the analyses of

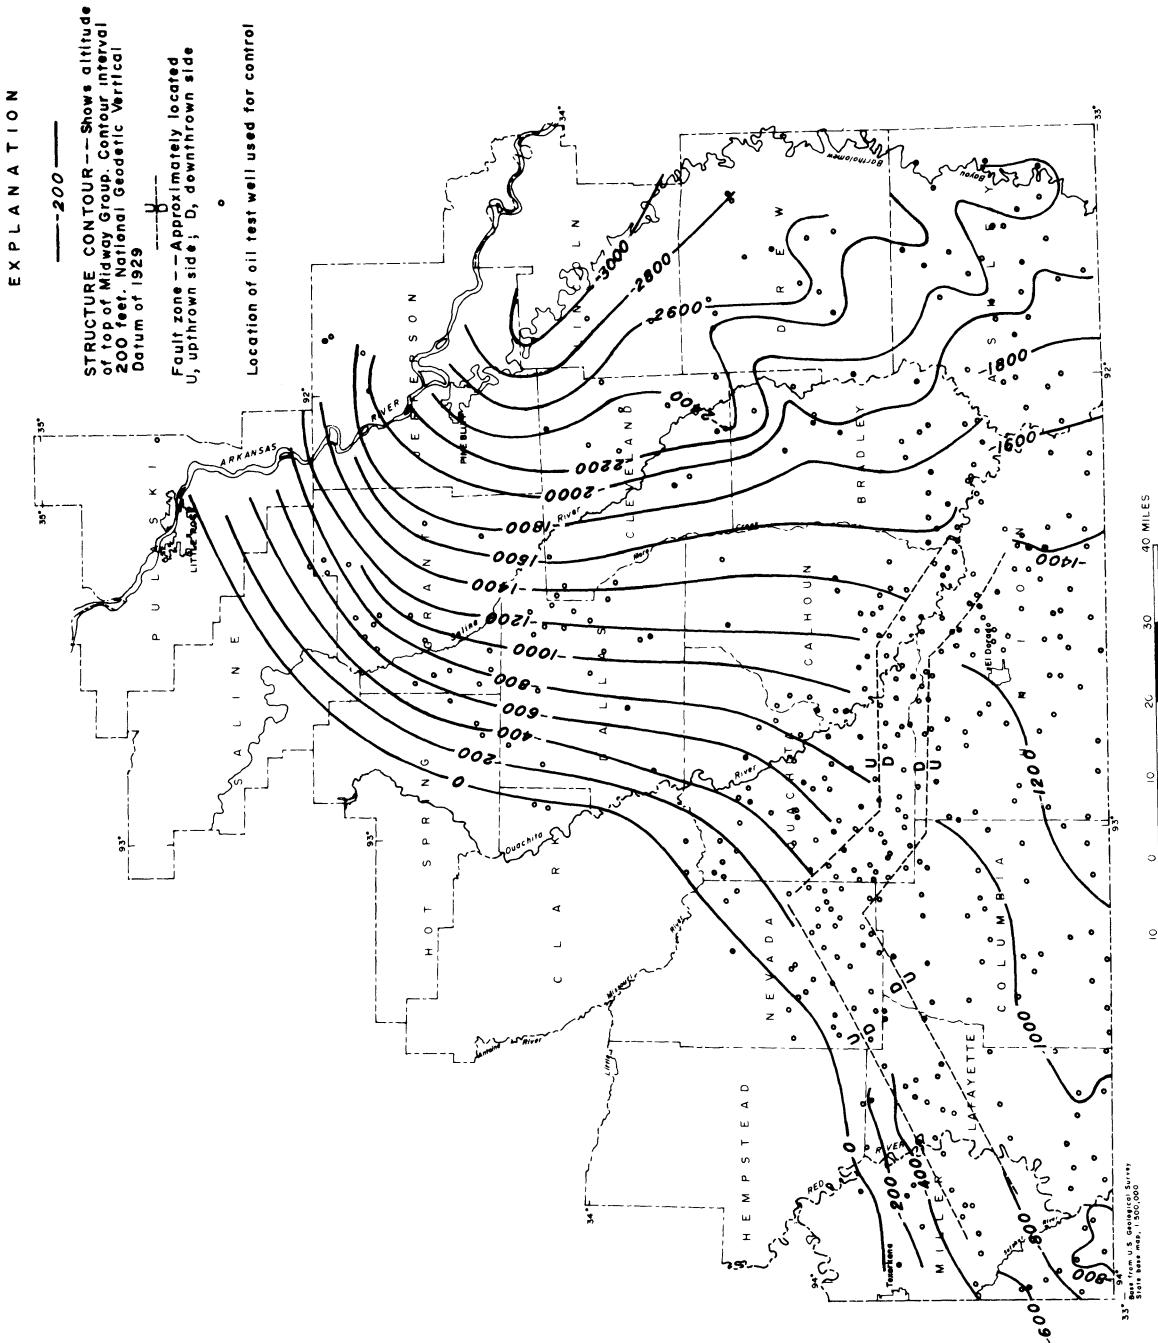

Figure 14.— Structural contours of the top of the Midway Group.

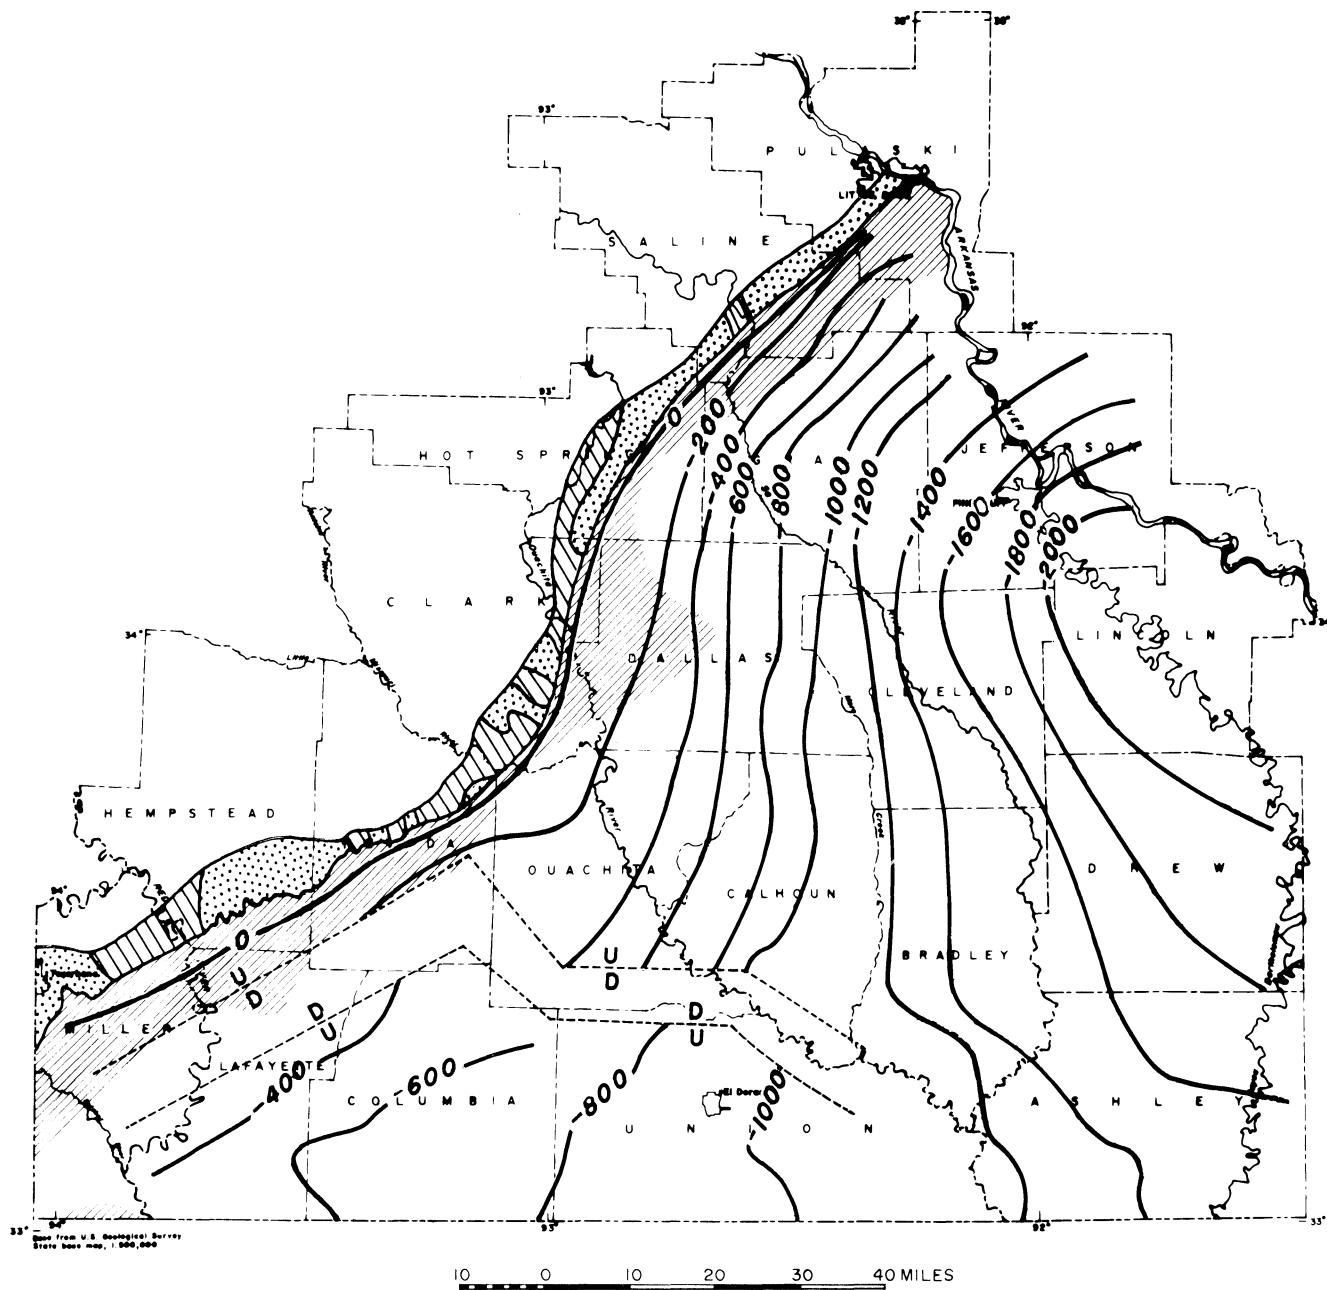

six samples (table 41) from Hot Spring and Saline Counties. With so few analyses concentrated in such a small area, very little can be said about the general quality of water in the formation. However, the available analyses do indicate a lower mineral concentration in the water from the Clayton Formation in Hot Spring County than in Saline County (table 41). Specific conductance averages 355 μmho in three samples from Saline County, and 149 μmho in three samples from Hot Spring County. The pH of the water from the two counties averages 7.2 and ranges from 5.5 to 8.1. The hardness of the water ranges from soft (12 mg/L CaCO_3) to hard (154 mg/L CaCO_3) in the two counties.

Wilcox Group, Undifferentiated

The lowermost unit of the Eocene section in Arkansas is the undifferentiated Wilcox Group. It consists of interbedded fine-grained sand, clay, silt, lignite, lignitic silt, and lignitic clay. It occurs either at the surface or in the subsurface throughout most of the project area. The exceptions are inliers of older rock (Midway Group and igneous rocks of Cretaceous age) in the northern part of the area. The outcrop area, the structural contours of the top of the formation, and areas of use are shown in figure 15. In the project area, the Wilcox Group ranges in thickness from 200 to 500 ft and in percentage of sand from 10 to 60 (fig. 16).

The Wilcox Group is identified on electric logs as the sequence of interbedded sand and clays above the distinctive clays of the Midway Group and below the more prominent sands of the Carrizo formation. The sand beds in the Wilcox Group are aquifers of local importance in or near the outcrop. Typically, the water in the sands of the Wilcox Group becomes brackish or saline within a short distance downdip and is unfit for most uses.

Figure 16.— Thickness and percentage of sand of the Wilcox Group undifferentiated (modified from Hosman and others, 1968).

The quantities of water available from the Wilcox Group varies. "About 200-300 gal/min is available from individual wells in southeastern Hot Spring and southwestern Grant counties" (Halberg and others, 1968). Throughout the rest of the project area, quantities of water adequate for household supplies or other small needs are generally available from the Wilcox. Water from the Wilcox Group varies in mineralization. Seven water samples taken from wells tapping the Wilcox in Miller County have specific conductances ranging from 152 to 2,170 μmho (table 42), with an average of 930 μmho . In Hot Spring County, the range in conductance for 16 samples is 16 to 661 μmho . The average pH for 30 analyses shown in table 42 is 7.3 and ranges from 5.0 to 8.9. Most of the pH values are between 6.2 and 8.4. Iron concentrations range from 0.0 to 9.7 mg/L and average 1.2 mg/L in Hot Spring County. For the analyses given in table 42, hardness, as calcium carbonate (CaCO_3), ranges from 2 to 143 mg/L and averages 35 mg/L.

Carrizo Sand

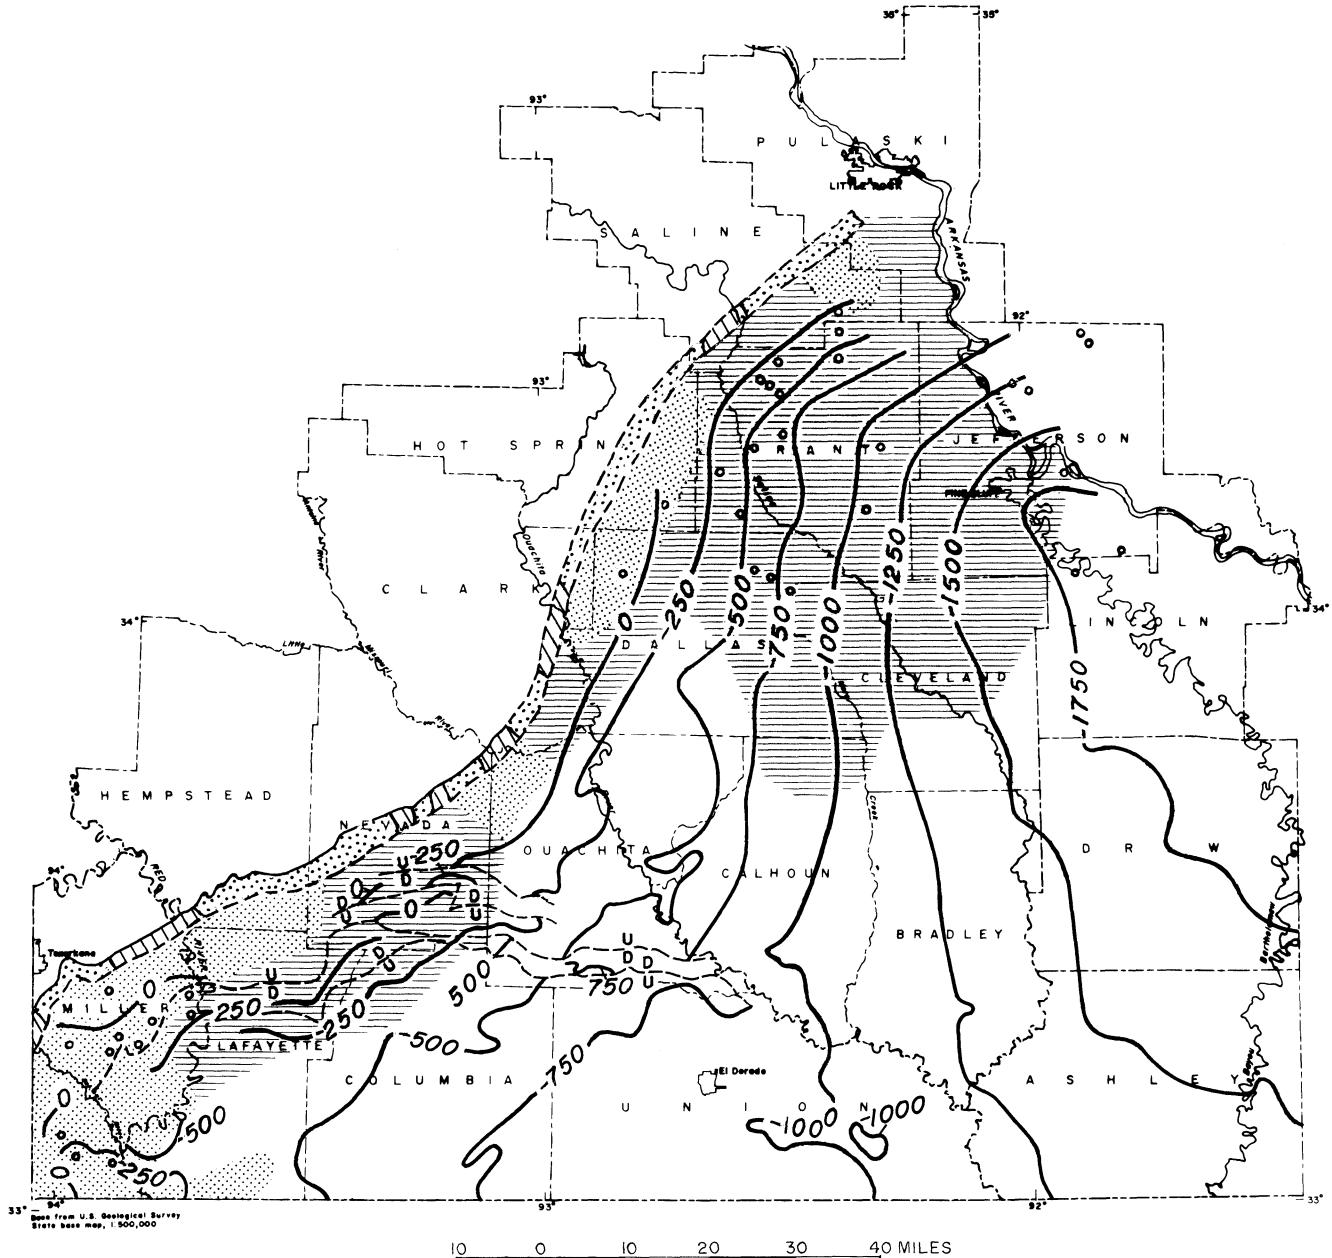

The Carrizo Sand, the basal formation of the Claiborne Group in Arkansas, crops out in central Miller, south Hempstead, and central Nevada Counties (Ludwig, 1972, p. 15), northwest Ouachita County (Albin, 1964 pl. 5), and possibly in southeast Clark County (Plebuch and Hines, 1969, p. A26). Its outcrop in west Dallas County (Plebuch and Hines, pl. 1) and east Hot Spring County (Halberg and others, 1968, pl. 1) has been inferred from updip projections of electric-log data. It is not known whether the Carrizo Sand crops out in Saline and Pulaski Counties, but it is present in the subsurface in north Grant County. The Carrizo Sand generally is present in the subsurface south and east of its outcrop. However, locally, it is missing, and the overlying Cane River Formation rests directly upon the Wilcox Group. Figure 17 shows

Area of use

Area of potential use

Figure 17.- Structural contours of the top and areas of use of the Carrizo Sand.

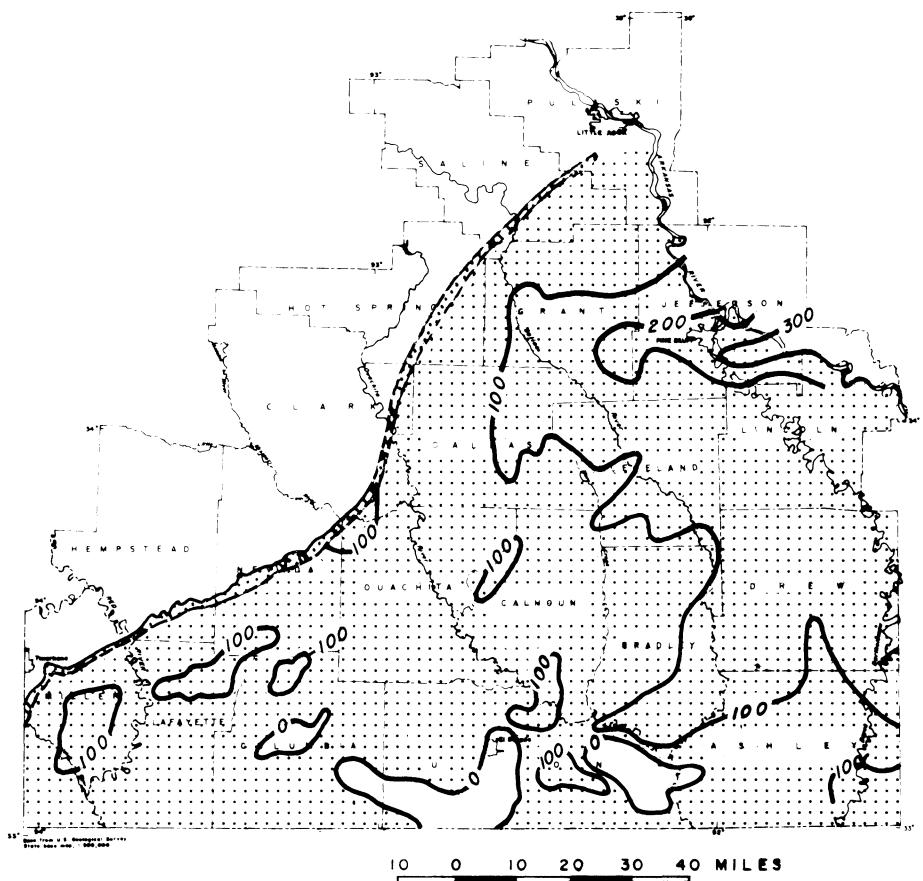

the outcrop area and structural contours of the top of the Carrizo Sand. In the lignite area, the Carrizo Sand is from a few feet to about 100 ft thick in or near its outcrop and generally increases downdip, to a maximum of about 300 ft in Jefferson County (fig. 18). Within the project area, more than 80 percent of the material composing the Carrizo Sand is sand (fig. 18).

Figure 19 shows the potentiometric surface for the Carrizo Sand. Movement of water is generally to the southeast. There is only a small amount of pumping from the Carrizo Sand and there are no significant cones of depression in the project area.

The amount of water used by wells tapping the Carrizo Sand in the lignite area is not large (table 2). Significant withdrawals from the Carrizo Sand in Miller, Hempstead, Nevada, Ouachita, and Hot Spring Counties add up to a total withdrawal of 0.33 Mgal/d. The Carrizo Sand is used as a source of water supply in other counties in the area, but the amount of water withdrawn is not significant.

Most wells tapping the Carrizo are used for domestic supplies. Very few municipal, industrial, or irrigation wells are completed in the Carrizo Sand. Yields range from 30 to 100 gal/min. In the southwestern part of the project area, low-yield flowing wells can be obtained.

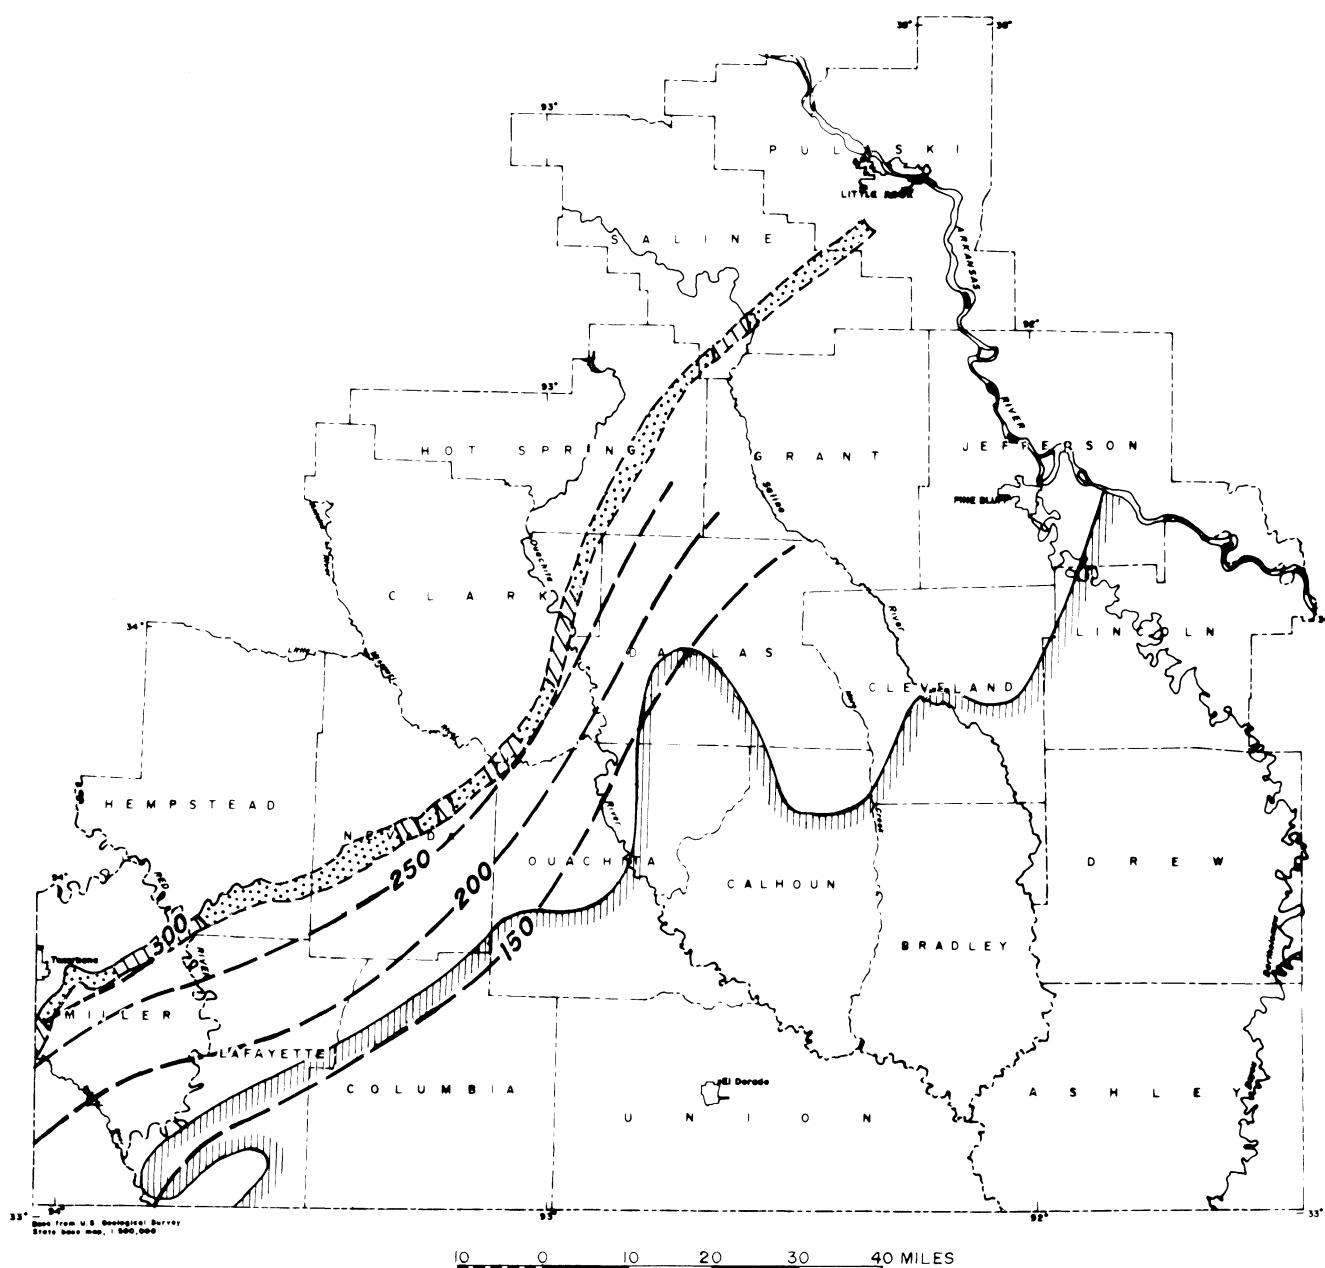

Information on the quality of water from the Carrizo Sand is available at a few places in the area. This information is given in table 43. Typically, the water is a sodium bicarbonate type and has a low to moderate mineral concentration. Downdip, water in the Carrizo Sand is unusable for some purposes because of increased chloride concentrations. The specific conductance of water from the Carrizo Sand differs from place to place, ranging from 24 μmho in a sample from Hot Spring County, to 4,680 μmho in a sample from Ouachita County. Figure 20 shows lines of equal specific conductance for the Carrizo

at 25 degrees Celsius. Interval as shown

Area of outcrop of Carrizo Sand. Dashed where approximately located

Area where outcrop of Carrizo Sand is covered by Quaternary deposits

Figure 20.— Specific conductance for the Carrizo Sand

Sand. Because of lack of available data, it was not possible to define contours in the central and eastern part of the project area. The specific conductance of water from the Carrizo Sand is generally less than 700 μmho . The pH of water in nine analyses, shown in table 43, ranges from 6.4 to 8.4 and averages 7.7. Water from the Carrizo Sand is generally soft (hardness, less than 60 mg/L), with the exception of one sample of water from the formation in Ouachita County that has a hardness of 79 mg/L (CaCO_3). Silica concentrations for five analyses, shown in table 43, averages 11.3 mg/L and ranges from 8.5 to 14 mg/L.

Cane River Formation

The Cane River Formation overlies the Carrizo Sand and is in turn overlain by the Sparta Sand. The Cane River occurs in the subsurface throughout most of the project area. The formation crops out in a zone along the northwestern boundary of the project area, from just south of Little Rock to near Texarkana (fig. 21). The Cane River Formation ranges in thickness from 150 ft, in Pulaski County, to 500 ft, in Jefferson County (fig. 22). The formation is generally from 21 to 60 percent sand. However, in west Grant, east Hot Spring, and central Miller Counties, the percentage of sand is 61 to 80. The percentage of sand decreases downdip (fig. 22). The potentiometric surface for the Cane River Formation is shown in figure 23.

Relatively few wells have been developed in the Cane River Formation. The formation is used mostly as a source of supply for wells in and near its updip limits. In this area, yields of as much as 920 gal/min are obtained (Ludwig, 1972). Total water use from the Cane River Formation in the lignite area was 3.48 Mgal/d in 1975 (table 2). The greatest water use was 2.47 Mgal/d in Lafayette County, with smaller amounts used in Miller, Nevada, Ouachita, Columbia, Dallas, and Hot Spring Counties.

EXPLANATION

Area of outcrop. Dashed where approximately located

Area of outcrop covered by Quaternary deposits

POTENTIOMETRIC CONTOUR -- Shows altitude of water level. Approximately located. Contour interval 50 feet. National Geodetic Vertical Datum of 1929

Approximate location of saltwater interface

Figure 23.- Potentiometric surface of the Cane River Formation.

The specific conductance of water from wells tapping the Cane River Formation ranges from 22 μmho , for a sample from Hot Spring County, to 4,360 μmho , for a sample from Ouachita County. The average specific conductance for 39 analyses, shown in table 44, is 443 μmho . Lines of equal specific conductance for the Cane River Formation are shown in figure 24. A general trend can be detected, with conductance increasing downdip, as might be expected. Contours are not fully developed in the central and eastern parts of the project area because sufficient data are not available at this time. The average pH is 7.5 and the range in pH is 4.5 to 8.8, with most values between 6.4 and 8.6. The average hardness for the analyses shown in table 44 is 35 mg/L (CaCO_3), which indicates soft water. However, the hardness of water in samples collected in Ouachita County is as much as 236 mg/L CaCO_3 . Bicarbonate averages 155 mg/L and ranges from 0 to 492 mg/L. Silica averages 12.6 mg/L and ranges from 8.5 to 25 mg/L. Chloride concentrations in water from the Cane River Formation are generally low except in the faulted zone in the south-central part of the project area. Within this zone, chloride concentrations can be so high that the water is unfit for some uses.

Sparta Sand

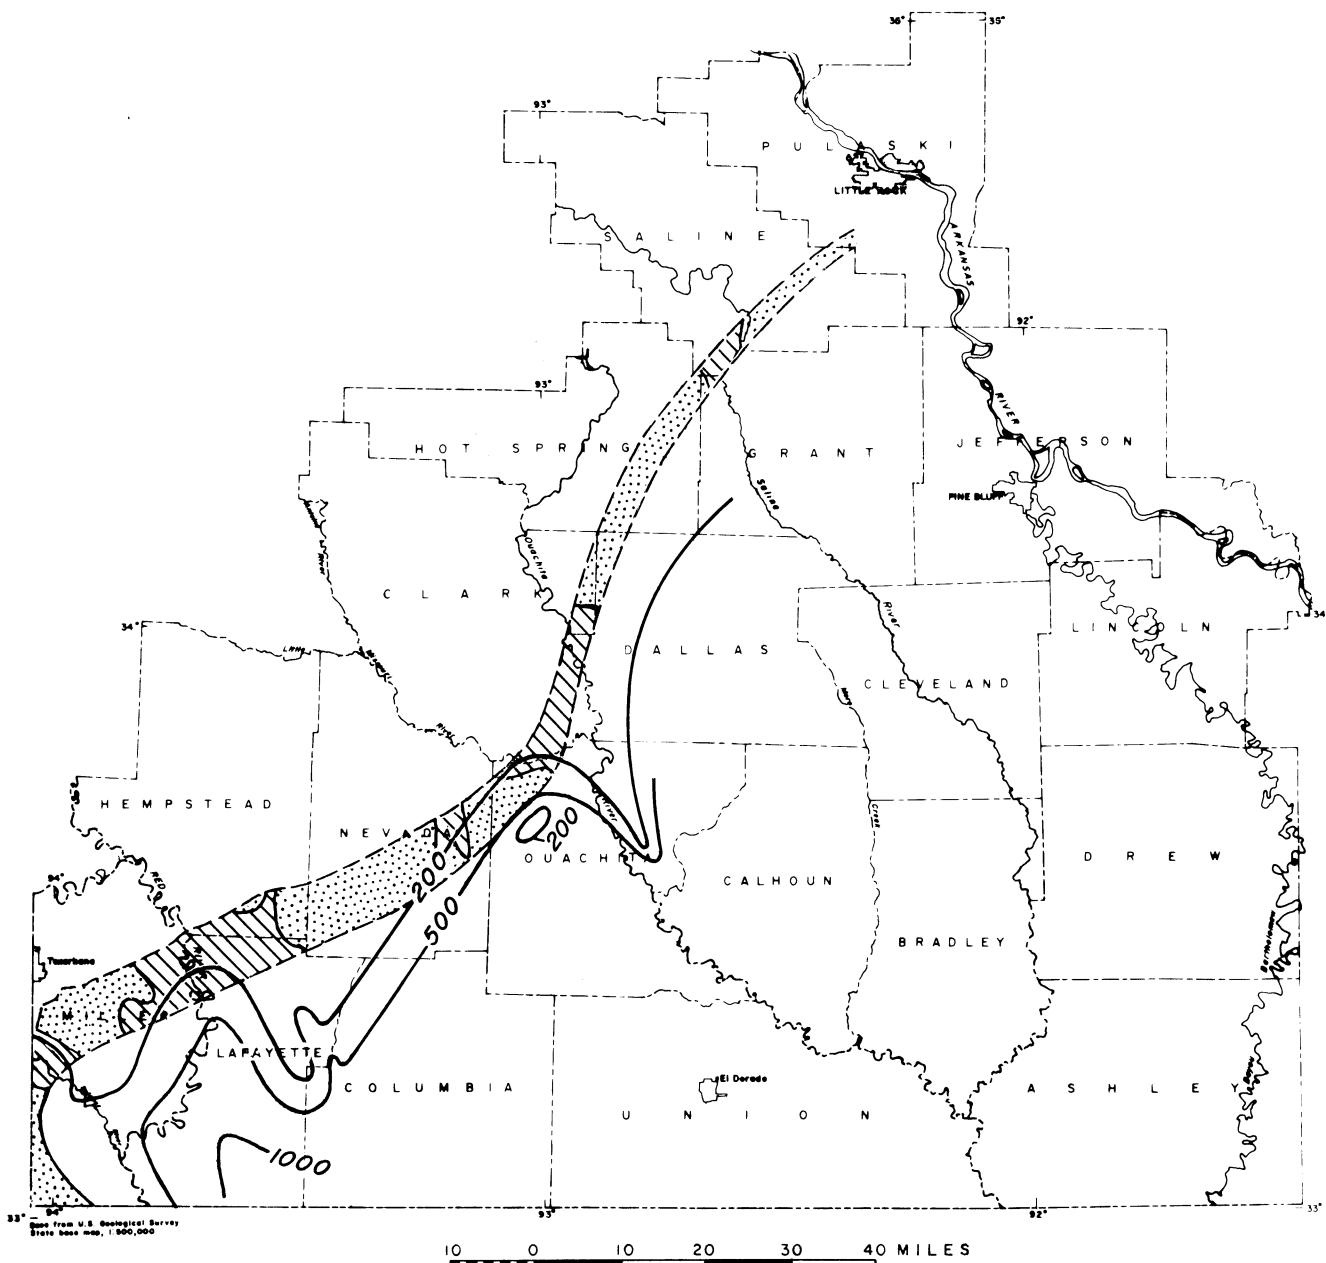

The Sparta Sand overlies the Cane River Formation and is overlain in turn by the Cook Mountain Formation. The Sparta is present throughout the entire project area. Areas of outcrop, structural contours of the top, and areas of use are shown in figure 25. The Sparta consists chiefly of beds of fine- to medium-grained sand in the lower part of the unit, and of beds of sand, clay, and lignite in the upper part. The formation is 300 to 900 ft thick and ranges from 21 to 100 percent sand in the project area (fig. 26). The thickness of the Sparta Sand increases and the percentage of sand generally decreases

Figure 26.— Thickness and percentage of sand of the Sparta Sand (modified from Hosman and others, 1968).

downdip. The formation dips toward the Mississippi River and southward toward the gulf. In the lignite area, the Sparta Sand is thinnest in southern Pulaski County and thickest in northern Drew County.

Figure 27 shows the potentiometric surface of the Sparta Sand. General movement of water is southeastward. Depressions exist around Magnolia, El Dorado, and Pine Bluff, where heavy pumping has significantly lowered water levels.

The Sparta Sand is the most productive aquifer in the lignite area. As shown in table 2, it is the source of significant withdrawals in 17 of the 20 counties in the lignite area. In 1975, total withdrawal from the Sparta Sand within the project area was 91.51 Mgal/d. The Sparta Sand is also a productive aquifer in eastern Arkansas, northern Louisiana, and in Mississippi. The Memphis aquifer, of which the Sparta Sand is the upper part, is a dependable source of water supply in northeast Arkansas and in Tennessee, Missouri, and Kentucky. About 350 Mgal/d was pumped from the Sparta Sand and the Memphis aquifer in 1965 in Arkansas, Kentucky, Louisiana, Mississippi, Missouri, and Tennessee. The use of water from the Sparta Sand and the Memphis aquifer in Arkansas increased about 30 percent from 1965 to 1975 and probably increased about the same amount in the other States.

The largest use of water from the Sparta Sand (53.82 Mgal/d in 1975) is in Jefferson County. Water withdrawn from the formation is used for municipal supply for Pine Bluff and smaller cities and industrial supply for two papermills and other industries. The second largest use of water from the Sparta Sand is in Union County (17.4 Mgal/d in 1975). The water is used for public supply by El Dorado and smaller cities and by several refineries and other industries. Substantial amounts of water from the Sparta are used in Columbia (6.02 Mgal/d in 1975) and Ouachita (4.28 Mgal/d in 1975) Counties. In 1975, use in other counties ranged from 0.13 Mgal/d to as much as 2.97 Mgal/d per county. Where

EXPLANATION

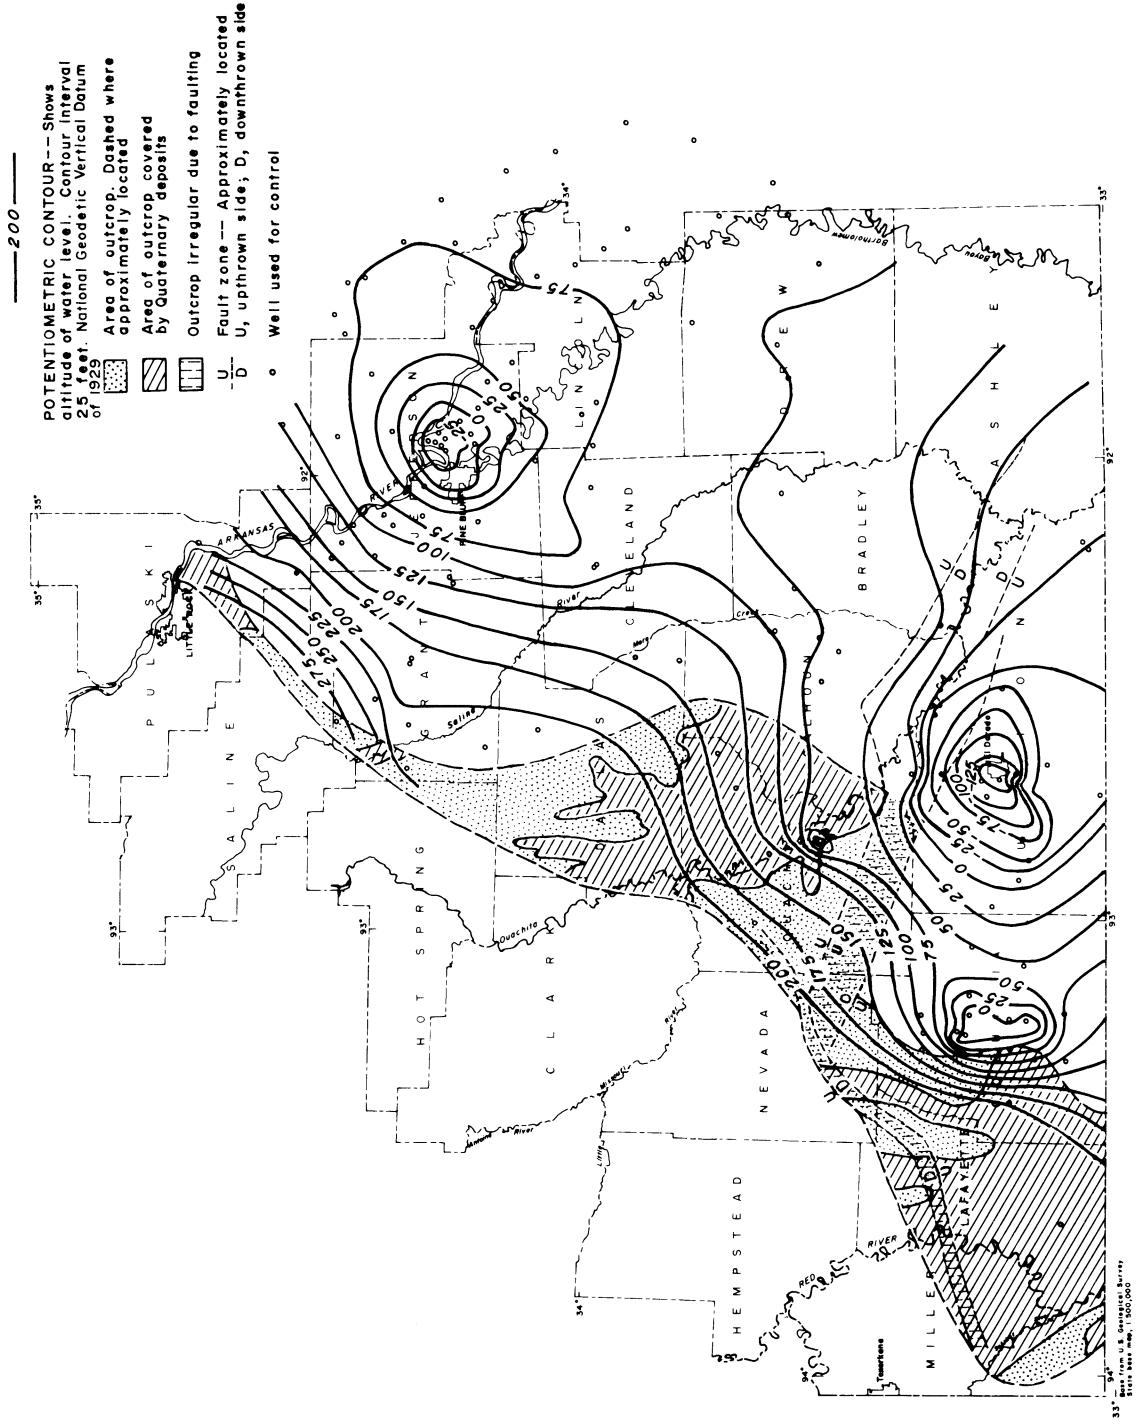

Figure 27- Potentiometric surface of the Sparta Sand.

present, the Sparta Sand is used as a source of municipal supply by most towns and cities in the project area.

Water in the Sparta Sand is generally soft and is a sodium bicarbonate type. Within the project area, dissolved-solids concentrations range from 24 to 1,320 mg/L and have an average of about 93 mg/L (table 45). Although the range in dissolved solids is large, the average indicates that in most areas water in the Sparta is only moderately mineralized. Specific conductance of water from the Sparta Sand ranges from 20 μmho in a sample from Lafayette County, to 4,610 μmho in a sample from Ouachita County. Figure 28 shows lines of equal specific conductance for the Sparta Sand. Conductance increases down-dip, as mineralization of the water increases. Also, locally, specific conductance may be higher than the general trend indicates. These highs are indicated by the closed lines on the map. The pH ranges from 4.0 to 8.8 and averages 7.4. Hardness of water from the Sparta Sand ranges from 1 to 238 mg/L and averages about 30 mg/L. Bicarbonate averages about 145 mg/L and ranges from 0 to 1,280 mg/L. Concentrations of silica range from 1.6 to 58 mg/L and average about 15.5 mg/L.

Cook Mountain Formation

The Cook Mountain Formation overlies the Sparta Sand and is overlain in turn by the Cockfield Formation. It is typically about 100 to 150 ft thick. The formation is composed of carbonaceous clay, lignite, and lenticular beds of sand ranging from a few inches to a few feet thick. These thin sand beds do not contain substantial amounts of water. However, the formation does furnish small amounts of water to shallow wells in its outcrop area in central Grant County east of the Saline River. The Cook Mountain Formation is of only minor importance as an aquifer in the project area.

EXPLANATION

— 500 —

LINE OF EQUAL SPECIFIC CONDUCTANCE, in micromhos per centimeter
at 25 degrees Celsius. Interval as shown

Area of outcrop of Sparta Sand.
Dashed where approximately located

Area where outcrop of Sparta Sand is covered by Quaternary deposits

Outcrop irregular due to faulting

Fault zone - - Approximately located
U D U, upthrown side; D, downthrown side

Figure 28.— Specific conductance for the Sparta Sand.

The results of analyses of 20 samples taken from wells tapping the Cook Mountain Formation are shown in table 46. Most of the samples were taken from wells in Ouachita and Grant Counties. Specific conductance ranges from 78 to 3,040 μmho and averages about 401 μmho . The average pH is about 6.4 and the range in values is from 5.3 to 8.3. Average hardness is about 98.5 mg/L and values range from 3 to 1,110 mg/L. Bicarbonate ranges from 8 to 210 mg/L and averages 56.0 mg/L.

Cockfield Formation

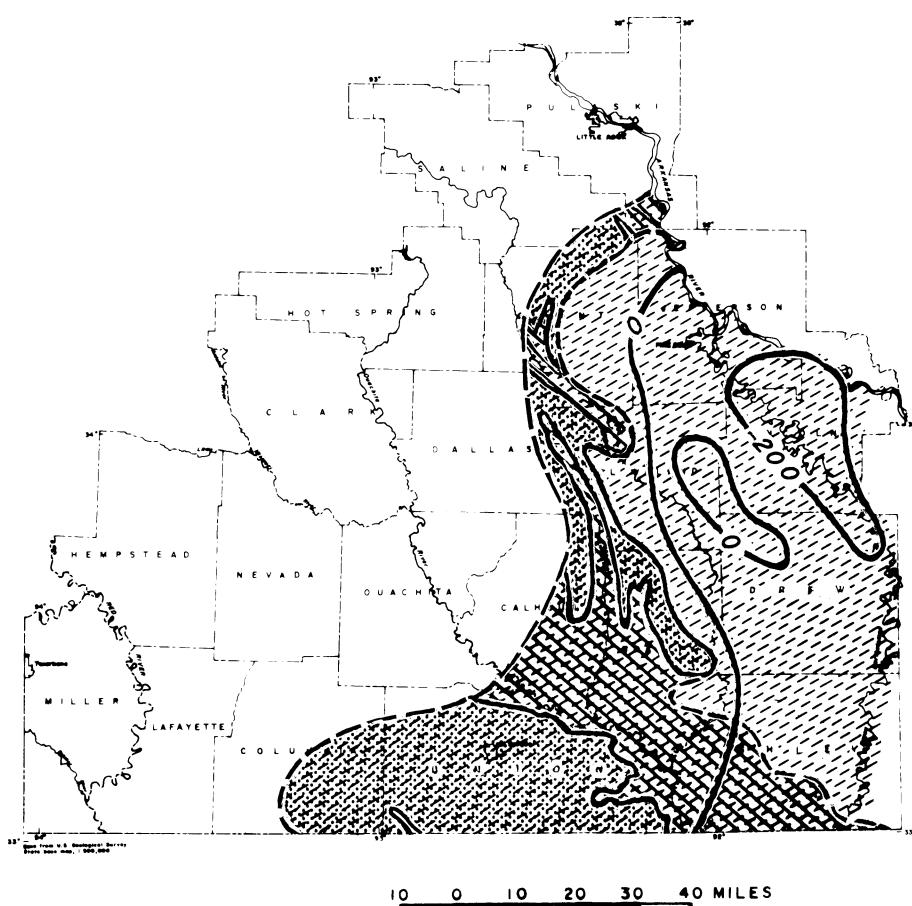

The Cockfield Formation overlies the Cook Mountain Formation and is in turn overlain by the Jackson Group, undifferentiated. The Cockfield is present throughout the eastern part of the project area. Areas of outcrop, structural contours of the top, and areas of use are shown in figure 29. The formation is about 200 ft thick and generally consists of 40 to 80 percent sand in the project area (fig. 30). Figure 31 shows the potentiometric surface for the Cockfield Formation. Movement of water is generally southward.

The Cockfield Formation is a significant source for ground water in 11 counties in the project area. The largest use is for domestic water supply. However, a few municipal and industrial wells also tap the aquifer. Within the project area, yields range from a few gallons per minute to 400 gal/min. The total water use in 1975 from the Cockfield Formation in the project area was 3.19 Mgal/d (table 2). The largest water use from the Cockfield is in Union (0.67 Mgal/d in 1975) and Cleveland (0.44 Mgal/d in 1975) Counties.

Water in the Cockfield is generally soft and is a sodium bicarbonate type. In the project area, dissolved solids range from 25 to 900 mg/L and average about 241 mg/L (table 47). Specific conductance ranges from 25 to 1,740 μmho and averages 435 μmho . Lines of equal specific conductance for the Cockfield are shown in figure 32. Closed contours in certain areas indicate local variations

Table 46.—Chemical analyses of samples taken from wells tapping the Cook Mountain Formation

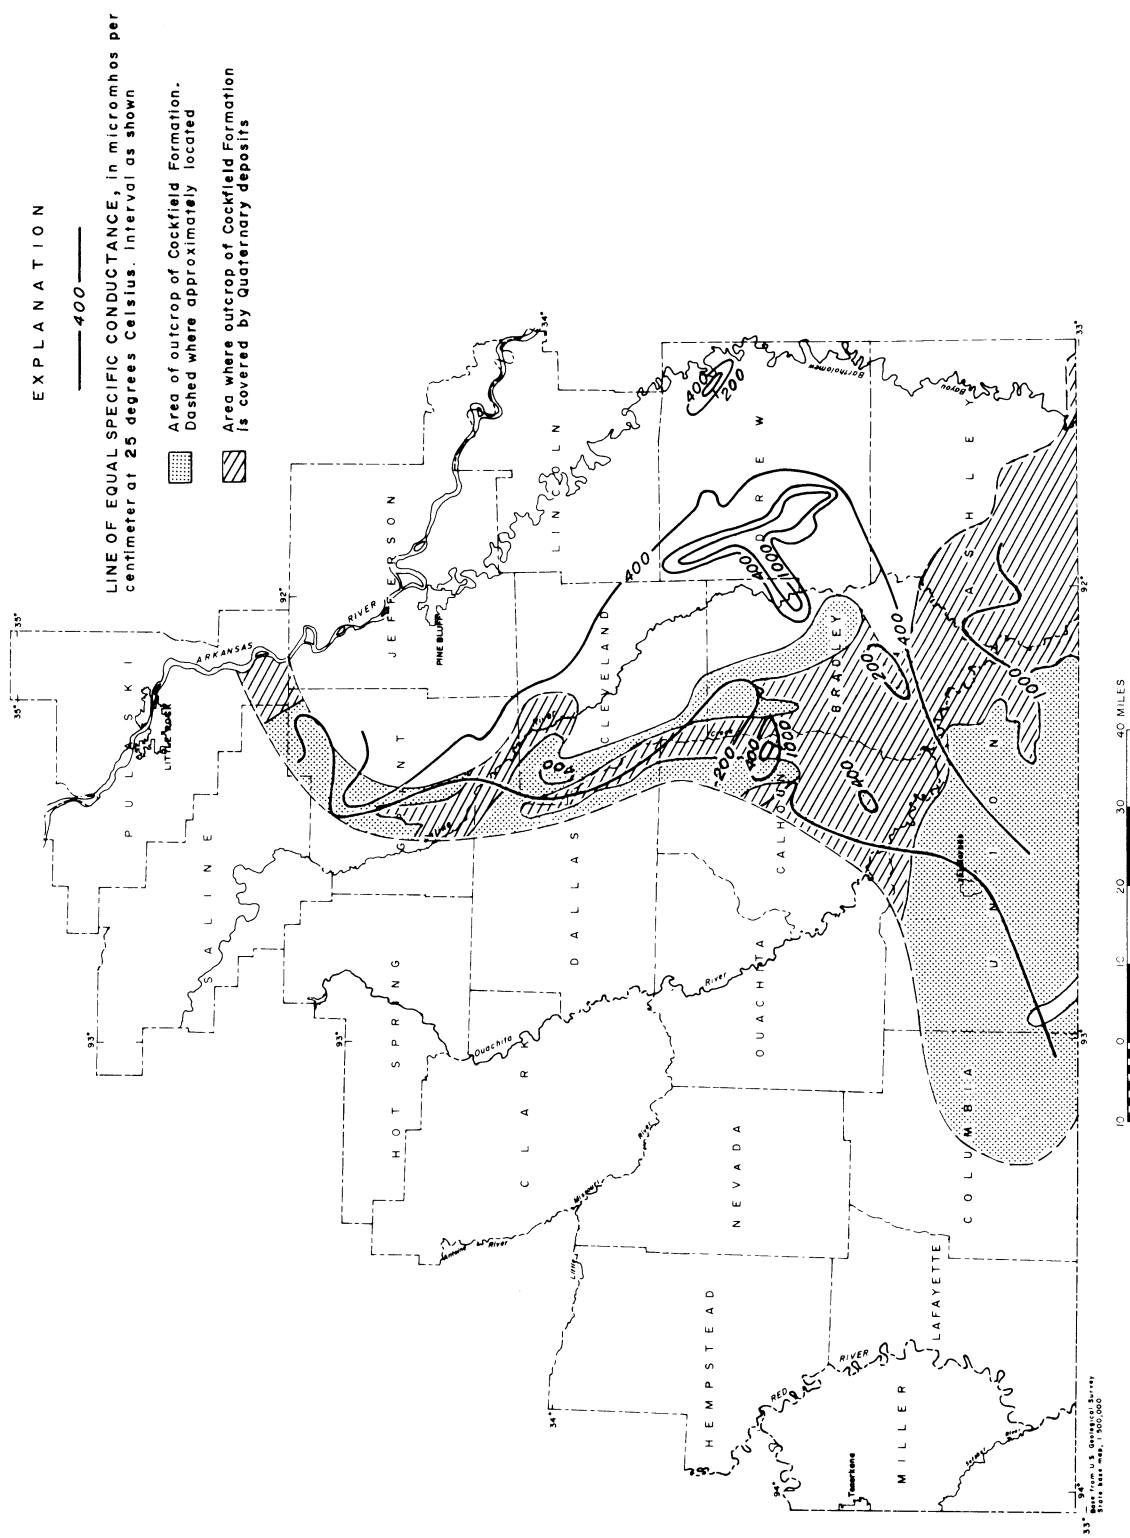

Figure 32.— Specific conductance for the Cockfield Formation.

that do not follow the general trend. Hardness ranges from 3 to 598 mg/L and the average is 54 mg/L. The average pH is 7.5 mg/L and the range in values is from 5.8 to 8.8 mg/L. Bicarbonate ranges from 7 to 428 mg/L and averages about 165 mg/L.

Jackson Group, Undifferentiated

The Jackson Group, undifferentiated, is the uppermost part of the deposits of Eocene age in the project area. It crops out in parts of Grant, Jefferson, Cleveland, Lincoln, Bradley, Drew, and Ashley Counties. The Jackson Group in the project area is a maximum of about 300 ft thick and consists mostly of clay, but it also includes beds of silt, sand, and lignite. The Jackson Group is not an important aquifer in the project area, but it does furnish small amounts of water to domestic wells in Bradley, Cleveland, Drew, Grant, Jefferson, and Lincoln Counties.

The quality of water from the Jackson Group is generally poor. Dissolved solids range from 78 to 5,330 mg/L and average about 852 mg/L (table 48). Average specific conductance is about 839 μmhos and values range from 35 to 5,490 μmho . Hardness ranges from 4 to 2,620 mg/L and averages about 379 mg/L, indicating that water from the Jackson is generally hard. Where large quantities of good-quality water are needed in the outcrop area of the Jackson Group, it is usually necessary to drill a deeper well into the Cockfield Formation or the Sparta Sand.

Deposits of Quaternary Age

The deposits of Quaternary age in the lignite area consist of gravel, sand, silt, and clay. These deposits include alluvium, which underlies the

flood plains of the streams, and terrace deposits, which are older alluvial deposits situated at higher altitudes above the present flood plains. Where present, these deposits are always at the surface; no younger formations overlie them. In many places the terrace deposits are dissected and function as independent aquifers. The locations of terrace and alluvial deposits are shown in figure 33. Figure 34 shows the thickness of the Quaternary deposits in the project area. The terrace deposits are from 0 to more than 100 ft thick and are commonly about 40 ft thick. The alluvial material varies in thickness from one drainage basin to another. Alluvium underlying the Red River flood plain ranges from 0 to 90 ft in thickness. Ouachita River alluvium ranges from 0 to 50 ft thick in most places. Alluvium underlying the Little Missouri River and the Saline River flood plains has a maximum thickness of about 40 ft. Alluvium deposited by smaller streams in the project area is generally less than 25 ft thick and commonly consists mostly of fine-grained material (silts and clays).

A large percentage of the total ground water used in the 20 counties containing the project area in 1975 (312.23 Mgal/d) is pumped from Quaternary aquifers. Most of this water (297.77 Mgal/d in 1975) is pumped from thick alluvial and terrace deposits which are beyond the eastern boundary of the project area. The water pumped outside the project boundary is used in Ashley, Drew, Lincoln, Jefferson, and Pulaski Counties. Less than 20 Mgal/d of water is pumped from Quaternary deposits within the project area. The largest use from the Quaternary aquifers in the lignite area is in Lafayette County (12.19 Mgal/d in 1975) followed by Miller County (1.74 Mgal/d in 1975).

The alluvial aquifer can furnish as much as 1,500 gal/min to properly constructed wells in Miller and Lafayette Counties (Ludwig, 1972), where

Figure 34.-Thickness of the Quaternary deposits (modified from Boswell and others, 1968).

the alluvium is as much as 90 ft thick. Many large-yielding irrigation wells tap the aquifer in these two counties. Little is known about the maximum yield of the alluvial aquifer in other parts of the lignite area. Yields of 240 gal/min were reported by Plebuch and Hines (1969, p. A29) for wells tapping the alluvium in the Ouachita River flood plain, south of Arkadelphia, in Clark County. Halberg and others (1968, p. 33) reported that the maximum yield of the alluvium in Grant and Hot Spring Counties was probably about 25 gal/min.

In the project area, water from the alluvium is generally moderately to highly mineralized, hard, and contains excessive iron (table 49). For the counties represented in table 49, the range in dissolved solids is 28 to 1,610 mg/L and the average is about 414 mg/L. Figure 35 shows the distribution of dissolved solids in the significant Quaternary aquifers (alluvium and terraces). Specific conductance ranges from 27 to 2,900 μmho and averages 523 μmho . Hardness averages about 158 mg/L and ranges from 6 to 864 mg/L. Dissolved iron concentrations are highly variable from place to place. For the counties represented in table 49, the maximum concentration of dissolved iron (24,000 mg/L) occurs in Drew County.

The only high yields (1,100 gal/min) reported from the terrace deposits have been in Lafayette County (Ludwig, 1972, p. 12). In other parts of the lignite area, the terrace deposits are known to furnish supplies sufficient for only domestic use. The terrace deposits form only a thin surface mantle in many areas of their occurrence and shallow dug and bored wells may tap both the terrace deposits and underlying older formations of Tertiary age.

Table 50 shows the results of the analyses of samples taken from wells tapping terrace deposits in 13 counties in the project area. The average specific conductance is about 345 μmhos and ranges from 21 to 4,130 μmho .

Table 49.—Chemical analyses of samples taken from wells tapping the alluvium

Well number	Date of sample	Temperature (°C.)	Color (platinum-cobalt units)	Specific conductance (μmho)	Bicarbonate (HCO_3^-) (mg/L)	Carbonate (CO_3^{2-}) (mg/L)	Hardness as calcium carbonate (CaCO ₃) (mg/L)	Non-carbonate (Na) (mg/L)	Dissolved calcium (Ca) (mg/L)	Dissolved magnesium (Mg) (mg/L)	Sodium adsorption ratio (Na/Mg)	Dissolved chloride (Cl) (mg/L)	Dissolved sulfate (SO ₄ ²⁻) (mg/L)	Dissolved fluoride (F) (mg/L)	Total iron (Fe) (mg/L)	Dissolved solids (sum of silica (SiO ₂), chloride (Cl), sulfate (SO ₄ ²⁻), and fluoride (F)) (mg/L)	Dissolved solids (sum of nitrates (NO ₃ ⁻), sulfates (SO ₄ ²⁻), and chlorides (Cl)) (mg/L)

Dissolved solids range from 47 to 406 mg/L and average about 179 mg/L. Hardness averages 70.9 mg/L and ranges from 4 to 399 mg/L. The pH averages about 6.59 and ranges from 4.3 to 8.6.

IMPACT OF LIGNITE DEVELOPMENT

The development of lignite resources in south Arkansas could have a variety of effects on available water resources. Direct effects will result from the mining activity, processing and conversion of the lignite, and land reclamation. Indirect effects will be related to population growth, increased public services, and expansion of commercial activities in the area.

An in-depth analysis of direct and indirect effects of lignite development is beyond the scope of this report. However, the reader should be aware of both types of effects because each will cause impacts on local and regional water resources in terms of quantity and quality. The following is an overview of the possible direct effects of lignite development.

The direct effects of lignite development include not only the obvious changes in the physical features of the land, but also changes in the hydrologic environment. The quantity and quality of surface and ground water can be affected.

Before mining can begin, the area where a pit is to be located and the perimeter area must be dewatered. This is generally done by using galleries of dewatering wells around the perimeter and a grid network of wells over the pit area. The dewatering directly affects the quantity and quality of surface and ground water.

In the project area, lignite generally is found in or near the outcrop areas of the Tertiary aquifers. (See figures 17, 21, 25, and 29.) In many places, large parts of these outcrop areas are covered by alluvial or terrace deposits of Quaternary age. Therefore, the mine excavations will, in some areas, cut through one or more shallow aquifers as well as significantly incise the Tertiary outcrop. Dewatering of these aquifers in the area of mining will probably have varying effects upon the ground-water regime, depending on the local hydrologic characteristics of the aquifers. The shallow Quaternary deposits, which are disconnected and function independently in many places, may be virtually "dried up" locally. This would affect primarily household supplies in the immediate area which might be tapping that aquifer. The dewatering of parts of the outcrop areas of the Tertiary aquifers will reduce water levels updip and downdip from the excavation sites. Updip water users may experience a continuing drop in water levels until eventually their wells may "dry up" and deeper wells may have to be drilled. Downdip, the effects could be equally or more severe.

When making plans for dewatering at a site in preparation for strip mining, the depth below land surface, and the thickness, of the saturated zone are of primary interest. In the outcrop areas of the Tertiary aquifers, water-table (unconfined) conditions exist and the saturated zone is nearer to the land surface than in areas where the aquifers are confined. Dewatering a portion of a Tertiary outcrop will require the pumpage of substantial quantities of water and could cause significant changes in water levels updip and downdip from the excavation site.

The most extensive and productive aquifers in the project area are the Cockfield Formation and the Sparta Sand. The outcrop areas of these aquifers are quite large (figs. 25 and 29) and contain most of the potential lignite

strip-mining sites (fig. 4) in the area. Figure 36 shows the saturated thickness of material in the outcrop areas of the Cockfield Formation and the Sparta Sand. An estimate of the depth at which the saturated zone will be encountered can be made by subtracting the altitude of the potentiometric surface (water-table in outcrop area) (figs. 27 and 31), at the desired site, from the land surface altitude at the same location. The land surface altitude can be estimated from U.S.G.S. topographic maps available from the Arkansas Geological Commission.

For example, near Hampton in Calhoun County at site A (figure 36) the land surface altitude estimated from a topographic map is approximately 200 feet. The altitude of the water table (fig. 31) in the Cockfield Formation at this site is 150 ft. The depth to the saturated zone is therefore approximately 50 ft. The saturated thickness of the Cockfield at this site is approximately 300 ft (fig. 36). Therefore, if an excavation 150 ft deep is planned, approximately 100 ft of saturated material will have to be dewatered.

Dewatering also stresses the surface-water regime. Changes in both quantity and quality may occur as a result of dewatering. Water discharged from the dewatering wells, and "mine water" pumped from the mines after excavation begins, must be disposed of. The most obvious receptacles will be local streams. Downstream from a mining area, receiving streams will experience increased flows that are directly proportional to the quantities of ground water that is necessary to pump for dewatering. The discharged ground water will also affect the quality of the stream. This change in quality will present no problem if the quality of the ground water is as

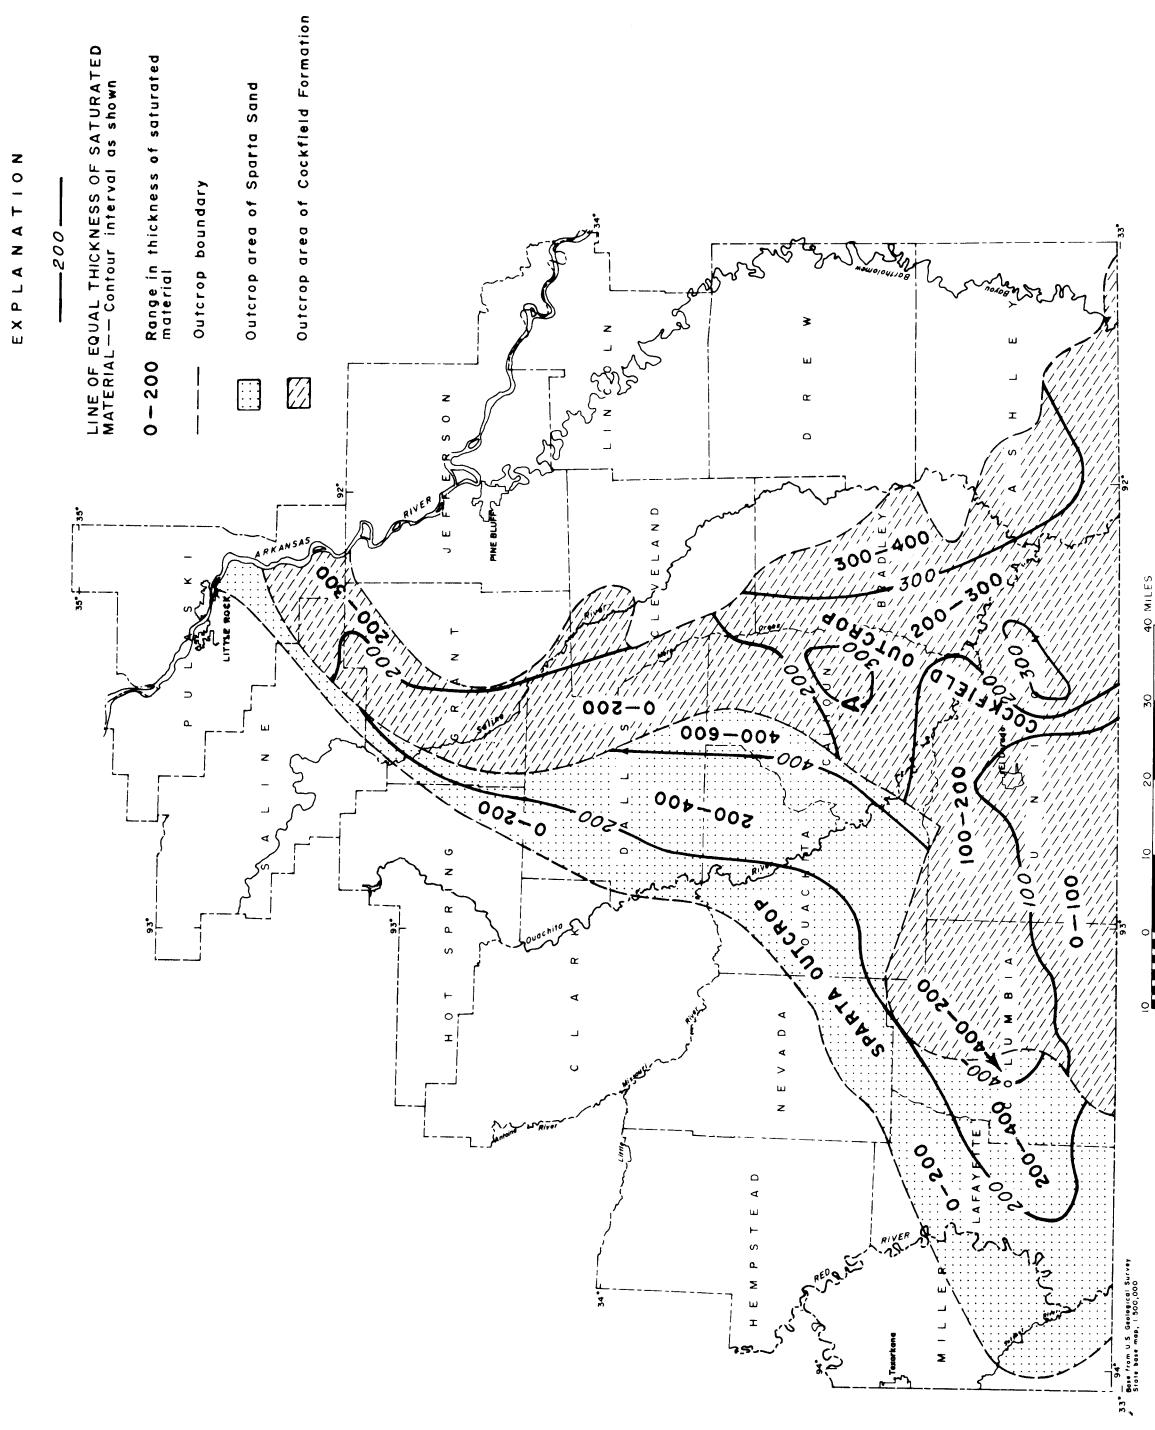

Figure 36. Saturated thickness of the Sparta Sand and Cockfield Formation in outcrop areas.

good or better than the water in the receiving streams. However, although by existing standards the quality of water in the streams may not be reduced, the character of the water may be altered somewhat. In some local areas, within the project area, near oil wells and associated saltwater pits, shallow wells are no longer used because of deterioration of water quality. "Chloride concentrations of as much as 46,250 mg/L have been found in the alluvium near Garland City in Miller County. The high chloride content of the water in the alluvial aquifer has made ground water in this area unsuitable for irrigation. The contamination is associated with oil-field activity in the area and is related directly to effluent seepage from brine-storage pits, some of which have been in use for as long as 30 years" (Ludwig, 1972). It would be wise to sample the shallow ground water at each mine site before development and select the best method for disposal if it shows poor quality.

When mining actually begins at a site, it may be necessary to divert certain streams in order to maintain the integrity of existing surface-drainage systems. These diversions, coupled with earth-moving activities associated with the mine excavation, will cause increased sediment loads in the streams unless controlled on the mining site. Greatly increased sediment loads could impact severely upon streambed biota. In most of the streams in the project area the habitat for benthic organisms is generally good (Arkansas Department of Pollution Control and Ecology, 1976 and 1977). A significant increase in sediment concentration in a stream over an extended period of time could reduce the variety of benthic organisms by virtually "silting up" existing habitat. This in turn would reduce the available food supply for larger aquatic life. Figure 7 shows the locations of stations where sampling for benthic organisms and sediment is continuing. In addition, plans are being made to establish other sampling sites as necessary through the mining period in order to monitor any changes that may occur.

When processing the lignite as it is removed, water will probably be used for ore-dust control when hauling, handling, and crushing the lignite, and for washing it to lower the ash and sulphur content. Road dust can be controlled in the mine area and on the haul roads by wetting these areas. A conservative estimate of water requirements can be made by assuming that roads and mine areas are kept wet through the deposition of water equal to the net annual-evaporation rate (Argonne National Laboratories, 1977). The average annual lake evaporation rate in the project area ranges from 46 in. in the southwest to 43 in. in the northeast. Dust can also be a problem during loading, unloading, and crushing the lignite. Generally, application of a water spray is the best means of preventing the dust from becoming airborne. Available data indicate that a consumptive use of 1 pound of water for every 50 pounds of ore handled and crushed is a reasonable estimate (Argonne National Laboratories, 1977). Washing requires about 1,500 to 2,000 gallons of water per ton of ore processed. However, about 80 percent of this water is recirculated.

Because lignite has a low heating value and a high moisture content, transporting it for long distances is not economical. Accordingly, the lignite will probably be utilized in near mine-mouth operations. In the case of a mine-mouth steam-electric generating plant, about 50 percent of the energy generated is expended in waste heat. Removal of this waste heat generally requires water for cooling purposes. Some of the lignite could be converted to gas or oil. The gasification and liquification procedures require water for processing and cooling.

There are two basic methods which require water for removing waste heat from steam-electric powerplants: once-through and evaporative cooling. In once-through cooling, the excess heat is transferred from the steam to water which has been withdrawn from a large body of water. The

heated water is then returned to its source where it is diluted and the heat dissipated. This cooling method requires withdrawal of large amounts of water and is used only where adequate surface-water flows are available. For streams that are considered as a source of cooling water and as recipients for plant discharge, the 7-day, 10-year low flow must be three times the amount required for withdrawal (Argonne National Laboratory, 1977). The Red and Ouachita Rivers are the only streams within the project area that could be considered as sources of water for a once-through cooling system. Consumption of water for plants using the once-through cooling system is $0.011\text{-}0.018(\text{ft}^3/\text{s})/\text{MWe}$ (megawatts of electricity) (Argonne National Laboratory, 1977).

In using evaporative cooling, excess heat is transferred to water which is then exposed to the air so that most of the heat is dissipated as some of the water evaporates. Cooling ponds or cooling towers may be used in evaporative cooling. Use of cooling ponds involves taking water from natural or artificial ponds, circulating it through the condenser and returning it to the ponds. When using a cooling tower, the heated water is cooled by the forced circulation of air through a falling spray of water. These methods require withdrawal of water from streams, reservoirs or ground-water sources to replace evaporation and spray drift losses. There should be adequate quantities of ground water available for this purpose almost anywhere in the project area. Water consumption by powerplants is $0.018\text{-}0.026(\text{ft}^3/\text{s})/\text{MWe}$ for plants using cooling towers, and $0.022\text{-}0.037(\text{ft}^3/\text{s})/\text{MWe}$ for those using cooling ponds (Argonne National Laboratory, 1977).

In the gasification and liquification processes, water is used in processing and cooling. In processing, water is used to generate steam and supply hydrogen for the reaction, and for quenching and sluicing and

control of air pollution. Many of the conversion reactions are highly exothermic, therefore, extensive process cooling is required. A gasification plant generating 250 million scf/day (standard cubic feet per day) of gas will require approximately 8-24 ft³/s of water. A gasification plant of this size or a liquification plant producing 100,000 barrels of oil per day will consume approximately 19 ft³/s of water (Argonne National Laboratories, 1977).

During reclamation, return of the overburden to the pits should be done as carefully as possible in order to restore, as nearly as possible, the integrity of the aquifers that have been disturbed. On properly reclaimed lands, infiltration and ground-water movement in the area will eventually approximate premining conditions. Streams diverted during mining should be rechanneled across the mine fill and premining gradients approximated as closely as possible. Postmining flows in such streams may differ somewhat due to changes in the ground-water/surface-water relationship throughout the mine area and that area in the perimeter affected by dewatering. The direction of water movement and (or) the quantity of water moving between stream and aquifer may differ after reclamation.

Soil stabilization plant cover should be established over the mine fill. This should be done immediately after filling the excavations in order to minimize erosion and avoid excessive sediment transport. Studies have concluded that strip-mined areas having greater than 10 in. of mean annual precipitation can be reclaimed without supplemental irrigation (Argonne National Laboratories, 1977). Mean annual precipitation for the project area is 48-52 in., so no supplemental water for irrigation of plant cover should be necessary.

SUMMARY AND RECOMMENDATIONS

Both water and lignite are important resources in south-central Arkansas. Removal and utilization of the lignite will undoubtedly have impacts upon the water resources. In order to effectively assess the significance of these impacts, existing baseline hydrologic conditions have been defined. Much of the information presented represents a compilation of data that is available as a result of previous water-resources investigations in the area. Data currently being collected in the project area are being added to the data base to more clearly define existing conditions.

Using data presented in this report as primary input, a digital model will be used to predict the effects of mining upon the ground-water regime. Various scenarios will be analyzed at each proposed mining site (fig. 7) to determine the drawdown necessary for dewatering, the quantities of water that will have to be pumped to maintain desired drawdown, and the distance from the excavation sites that cones of depression will significantly affect water levels.

Collection of data should continue at its current level in the project area for a minimum of 3 years. Flow duration, flood frequency, and low-flow frequency are already determined for the major streams. However, sediment transport and stream biota should be well defined in the area before mining begins. Also, seasonal ground-water fluctuations and local water-level patterns should be defined. Ground-water samples should be collected in the proposed mining areas to check the quality of water in the formations that are likely to be disturbed. A skeleton data-collection network should be maintained throughout the mining period to monitor changes as they occur. These data could be used to check the accuracy of long-term predictions and

identify unforeseen problems. Early detection of problems in the hydrologic environment is vital to proper and timely corrective action.

Lignite is a very valuable resource for Arkansas. Aside from its obvious asset as an energy source, the mining and associated activity could be a stimulus upon the economy of the south-central part of the State. However, care should be taken that in utilizing one resource, irreversible damage is not done to another.
